- (j) When silicon-killed steel is specified.
- (k) For plate under 40 mm (1.5 in.), manganese contents are 0.70 to 1.35% or up to 1.60% if carbon equivalents do not exceed 0.47%. For plate over 40 mm (1 to 5 in.), ASTM A 841 specifies manganese contents of 1.00 to 1.60%.

Alloying elements are also selected to influence transformation temperatures so that the transformation of austenite to ferrite and pearlite occurs at a lower temperature during air cooling. This lowering of the transformation temperature produces a finer-grain transformation product, which is a major source of strengthening. At the low carbon levels typical of HSLA steels, elements such as silicon, copper, nickel, and phosphorus are particularly effective for producing fine pearlite. Elements such as manganese and chromium, which are present in both the cementite and ferrite, also strengthen the ferrite by solid-solution strengthening in proportion to the amount dissolved in the ferrite.

Carbon markedly increases the amount of pearlite in the microstructure and is one of the more potent, as well as economical, strengthening elements. However, higher carbon contents reduce weldability and the impact toughness of steel. Increases in pearlite content are also ineffective in improving yield strength, which is often the main strength criterion in structural applications.

In the presence of alloying elements, the practical maximum carbon content at which HSLA steels can be used in the as-rolled condition is approximately 0.20%. Higher levels of carbon tend to form martensite or bainite in the microstructure of as-rolled steels, although some of the higher-strength low-alloy steels have carbon contents that approach 0.30%. Many of the proprietary microalloyed HSLA steels have carbon contents of 0.06% or even lower, yet are still able to develop yield strengths of 345 to 620 MPa (50 to 90 ksi). Carbon levels as low as 0.03% are utilized in some alloy designs. The required strength is developed by the combined effect of:

- Fine grain size developed during controlled hot rolling and enhanced by microalloyed elements (especially niobium)
- Precipitation strengthening caused by the presence of vanadium, niobium, and titanium in the composition

Nitrogen in amounts up to about 0.02% has been used to obtain strengths typical of HSLA steels and at reasonable cost. For carbon and carbon-manganese steels, such a practice is limited to light-gage products because the increase in strength is accompanied by a drop in notch toughness. In some applications, nitrogen contents are limited to 0.005%. Nitrogen additions to high-strength steels containing vanadium have become commercially important because such additions enhance precipitation hardening. The precipitation of vanadium nitride in vanadium-nitrogen steels also improves grain

refinement because it has a lower solubility in austenite than vanadium carbide (Fig. 15). The total effect of nitrogen on yield strength is discussed in the section "Tensile Properties" in this article.

Fig. 15 Solubility product versus temperature for eight carbonitride compounds in austenite

Manganese is the principal strengthening element in plain carbon high-strength structural steels when it is present in amounts over 1%. It functions mainly as a mild solid-solution strengthener in ferrite, but it also provides a marked decrease in the austenite-to-ferrite transformation temperature. In addition, manganese can enhance the precipitation strengthening of vanadium steels (Table 12) and, to a lesser extent, niobium steels.

Silicon. One of the most important applications of silicon is its use as a deoxidizer in molten steel. It is usually present in fully deoxidized structural steels in amounts up to 0.35%, which ensures the production of sound, dense ingots. Silicon has a strengthening effect in low-alloy structural steels. In larger amounts, it increases resistance to scaling at elevated temperatures. Silicon has a significant effect on yield strength enhancement by solid-solution strengthening (Fig. 9) and is widely used in HSLA steels for riveted or bolted structures. It can be used up to 0.30% in weldable steels; higher amounts produce a deterioration in notch toughness and weldability (Ref 23).

Copper. Approximately 0.20% copper is used to provide resistance to atmospheric corrosion. Its effect on resistance to corrosion is enhanced when phosphorus is present in amounts greater than about 0.05%.

Copper in levels in excess of 0.50% also increases the strength of both low- and medium-carbon steels by virtue of ferrite strengthening, which is accompanied by only slight decreases in ductility. In amounts over about 0.60%, copper can precipitate as ϵ -copper, which precipitation strengthens the ferrite. Copper can be retained in solid solution even at the slow rate of cooling obtained when large sections are normalized, but it is precipitated out when the steel is reheated to

about 510 to 605 °C (950 to 1125 °F). At about 1% copper, the yield strength is increased by about 70 to 140 MPa (10 to 20 ksi), regardless of the effects of other alloying elements. Copper in amounts up to 0.75% is considered to have only minor adverse effects on notch toughness or weldability.

Copper precipitation hardening gives the steel the ability to be formed extensively (while still low in strength) and then precipitation hardened as a complex shape or welded assembly. This avoids the distortion or difficulty encountered by quenching compared with components made from conventionally heat-treated alloy steel.

Steels containing more than 0.50% Cu can exhibit hot shortness, with the result that cracks and a rough surface may develop during hot working. Careful control of oxidation during heating and prevention of overheating can minimize these conditions. The addition of nickel in amounts equal to at least one-half the copper content is very beneficial to the surface quality of copper-bearing steels. Copper is also added in amounts between 0.25-0.35% to improve resistance to hydrogen-induced cracking in aqueous environments and H₂S environments.

Phosphorus is an effective solid-solution strengthener in ferrite (Fig. 9). It also enhances corrosion resistance but causes a decrease in ductility. Phosphorus at low levels (<0.05% P) can also cause embrittlement through segregation to the prior-austenite grain boundaries.

The atmospheric-corrosion resistance of steel is increased appreciably by the addition of phosphorus, and when small amounts of copper are present in the steel, the effect of the phosphorus is greatly enhanced. When both phosphorus and copper are present, there is a greater beneficial effect on corrosion resistance than the sum of the effects of the individual elements.

Chromium is often added with copper to obtain improved atmospheric-corrosion resistance. Upon exposure to the atmosphere, a steel composition with about 0.12% P, 0.85% Cr, and 0.40 Cu% develops a particularly adherent, dense oxide coating that is characteristic of weathering steels.

Nickel can be added in amounts up to about 1% in several HSLA steels and in amounts up to 5% for high-strength heat-treated alloy grades. It moderately increases strength by solution hardening of the ferrite. In HSLA steels, it enhances atmospheric-corrosion resistance and, when present in combination with copper and/or phosphorus, increases the seawater corrosion resistance of steels. Nickel is often added to copper-bearing steels to minimize hot shortness.

Molybdenum in hot-rolled HSLA steels is used primarily to improve hardenability when transformation products other than ferrite-pearlite are desired. For example, molybdenum is an essential ingredient for producing as-rolled acicular ferrite steels. In addition, it effectively enhances elevated-temperature properties.

Molybdenum (0.15 to 0.30%) in microalloyed steels also increases the solubility of niobium in austenite, thereby enhancing the precipitation of NbC(N) in the ferrite. This increases the precipitation-strengthening effect of Nb(C,N). Molybdenum has also been shown to join the Nb(C,N) precipitates, which further raises the yield strength.

Niobium. Small additions (0.03 to 0.05% Nb) of niobium increase yield strength by a combination of precipitation strengthening (Fig. 12) and grain refinement. Niobium is a more effective grain-refining element than vanadium because niobium carbide is more stable in austenite than vanadium carbide at typical rolling temperatures. The lower solubility of niobium carbide in austenite (Fig. 15) provides more stable precipitate particles, which pin the austenite grain boundaries and thus retard austenite grain growth.

Aluminum is widely used as a deoxidizer and was the first element used to control austenite grain growth during reheating. During controlled rolling, niobium and titanium are more effective grain refiners than aluminum. Titanium (Fig. 13(a)), niobium, zirconium, and vanadium are also effective grain growth inhibitors during reheating. However, for steels that are heat treated (quenched and tempered), these four elements may have adverse effects on hardenability because their carbides are quite stable and difficult to dissolve in austenite prior to quenching.

Vanadium strengthens HSLA steels by both precipitation hardening the ferrite and refining the ferrite grain size. The precipitation of vanadium carbonitride in ferrite can develop a significant increase in strength that depends not only on the rolling process used, but also on the base composition. Carbon contents above 0.13 to 0.15% and manganese content of 1% or more enhances the precipitation hardening, particularly when the nitrogen content is at least 0.01%. Grain size refinement depends on thermal processing (hot rolling) variables, as well as vanadium content.

Titanium is unique among common alloying elements in that it provides both precipitation strengthening and sulfide shape control. Small amounts of titanium (<0.025%) are also useful in limiting austenite grain growth (Fig. 13(a)). However, it is useful only in fully killed (aluminum deoxidized) steels because of its strong deoxidizing effects. The versatility of titanium is limited because variations in oxygen, nitrogen, and sulfur affect the contribution of titanium as a carbide strengthener.

Zirconium can also be added to killed high-strength low-alloy steels to improve inclusion characteristics, particularly in the case of sulfide inclusions, for which changes in inclusion shape improve ductility in transverse bending.

Boron has no effect on the strength of normal hot-rolled steel but can considerably improve hardenability when transformation products such as acicular ferrite are desired in low-carbon hot-rolled plate. Its full effect on hardenability is obtained only in fully deoxidized (aluminum-killed) steels.

Rare-earth elements, principally cerium, lanthanum, and praseodymium, can be used to provide shape control of sulfide inclusions. Sulfide inclusions, which are plastic at rolling temperatures and thus elongate and flatten during rolling, adversely affect ductility in the short transverse (through-thickness) direction. The chief role of rare-earth additives is to produce rare-earth sulfide and oxysulfide inclusions, which have negligible plasticity at even the highest rolling temperatures. Excessive amounts of cerium (>0.02%) and other rare-earth elements lead to oxide or oxysulfide stringers that may affect directionality. Treatment with rare-earth elements is seldom used because they produce relatively dirty steels. Treatment with calcium is preferred for sulfide inclusion shape control.

Controlled Rolling. The hot-rolling process has gradually become a much more closely controlled operation, and controlled rolling is now being increasingly applied to microalloyed steels with compositions carefully chosen to provide optimum mechanical properties at room temperature. Controlled rolling is a procedure whereby the various stages of rolling are temperature controlled, with the amount of reduction in each pass predetermined and the finishing temperature precisely defined. This processing is widely used to obtain reliable mechanical properties in steels for pipelines, bridges, offshore platforms, and many other engineering applications. The use of controlled rolling has resulted in improved combinations of strength and toughness and further reductions in the carbon content of microalloyed HSLA steels. This reduction in carbon content improves not only toughness but also weldability.

The basic objective of controlled rolling is to refine and/or deform austenite grains during the rolling process so that fine ferrite grains are produced during cooling. Controlled rolling can be performed on carbon steels but is most beneficial in steels with vanadium and/or niobium additions. During hot rolling, the undissolved carbonitrides of vanadium and niobium pin austenite grain boundaries and thus retard austenite grain growth. In carbon steels, however, the temperatures involved in hot rolling lead to marked austenite grain growth, which basically limits any benefit of grain refinement by controlled rolling. Controlled rolling is performed on strip, plate, and bar mills but not on continuous hot strip mills. On a hot strip mill, the water cooling on the runout table ensures a fine grain size.

The three methods of controlled rolling are:

- Conventional controlled rolling
- Recrystallization controlled rolling
- Dynamic recrystallization controlled rolling

These three methods use different techniques for grain refinement, but they are all preceded by a roughing operation to refine grain size by repeated recrystallization. In the roughing stage, stable carbonitride precipitates are desirable because they pin the grain boundaries of the recrystallized austenite and thus prevent their growth. Niobium is more effective than vanadium in preventing austenite grain growth during rolling because niobium forms precipitates that are less soluble than vanadium carbide in austenite (Fig. 15). Roughing can achieve austenite grain sizes on the order of 20 μm (0.8 mil). The austenite grains are then either deformed or further refined by controlled rolling during finishing operations.

Conventional controlled rolling is based on the deformation, or flattening (pancaking), of austenite grains so that a large number of nucleation sites exist on the deformed austenite grain boundaries and on the deformation bands with the austenite grains. These nucleation sites allow the formation of very fine-grain ferrite during transformation cooling. This process requires a total reduction of up to 80% in a temperature range where the austenite deforms but does not recrystallize.

Niobium is the most effective alloying element for grain refinement by conventional controlled rolling. During the rolling reductions at temperatures below 1040 °C (1900 °F), the niobium in solution suppresses recrystallization by solute drag or by strain-induced Nb(C,N) precipitation on the deformed austenite and slip planes. The strain-induced precipitates are too large to affect precipitation strengthening but are beneficial for two reasons: They allow additional suppression of recrystallization by preventing migration of austenite grain sub-boundaries, and they provide a large number of nuclei in the deformed austenite for the formation of fine ferrite particles during cooling. The strain-induced precipitates in the austenite detract from the precipitation-hardening potential of the ferrite by removing the available niobium from austenite solid solution. Nevertheless, a useful measure of precipitation strengthening is possible in controlled-rolled niobium steels.

The controlled rolling of niobium steels can lead to ferrite grain sizes in the range of 5 to 10 µm (ASTM grain size numbers 10 to 12). General combinations of yield strength and ductile-brittle transition temperatures for niobium steel with various compositions and section sizes are shown in Fig. 16. Because the precipitation of Nb(CN) in the austenite during hot rolling retards recrystallization and raises the temperature at which recrystallization of austenite ceases (the recrystallization stop temperature), a broader temperature range is possible for hot working the steel to produce highly deformed austenite. The optimum amount of niobium to suppress recrystallization between passes can be as little as 0.02%. Titanium, zirconium, and vanadium are not as effective as niobium in raising the recrystallization stop temperature. Titanium and zirconium nitride formed during solidification and upon cooling of the slab do not readily dissolve upon reheating to hot-rolling temperatures. Although these nitrides may prevent grain coarsening upon reheating, they are not effective in preventing recrystallization, because insufficient titanium or zirconium remains in solution at the rolling temperature to precipitate on deformed austenite during boundaries during hot-rolling and thus suppress austenite recrystallization. Vanadium, on the other hand, is so soluble that precipitation does not readily occur in the austenite at normal hot-rolling temperatures. The concentrations of niobium, titanium, vanadium, carbon, and nitrogen; the degree of strain; the time between passes; the strain rate; and the temperature of deformation all influence recrystallization during hot working.

(a)

(b)

Recrystallization Controlled Rolling. Although conventional controlled rolling can lead to very fine ferrite grain sizes, the low finishing temperature (750 to 900 °C, or 1400 to 1650 °F) of this method leads to increased rolling loads for heavy plate and thick-walled seamless tube. For thicker sections, recrystallization controlled rolling is used to refine austenite grain size. This process can result in ferrite grain sizes on the order of 8 to 10 µm (0.3 to 0.4 mil).

Recrystallization controlled rolling involves the recrystallization of austenite at successively lower temperatures below roughing temperatures but still above 900 °C (1650 °F). Recrystallization should not be sluggish for this method to succeed, and thus vanadium can be beneficial because vanadium carbide is readily dissolved at rolling temperature and therefore unavailable for suppressing recrystallization. However, vanadium steels require stable carbonitrides, such as titanium nitride, to retard grain growth after recrystallization. Niobium steels, on the other hand, can undergo recrystallization controlled rolling at higher temperatures with Nb(C,N) precipitates eventually forming. This precipitation of Nb(C,N) will restrict austenite grain growth and may preclude the need for a titanium addition.

Dynamic recrystallization controlled rolling is used when there is insufficient time for recrystallization between rolling passes. This process initiates recrystallization during deformation and requires appreciable reductions (for example, 100%) to achieve an austenite grain size of 10 µm (0.4 mil). With low-temperature finishing, dynamic recrystallization can result in ferrite grain as fine as 3 to 6 µm (0.12 to 0.24 mil).

Interpass Cooling in Controlled Rolling. One of the major drawbacks with conventional controlled rolling is excessive processing time, especially on single-stand mills lacking facilities for removing plates off line during the hold period. Therefore, some investigations have examined the possibility of reducing processing time by the application of accelerated cooling both during the delay period and between individual roughing and finishing passes. In general, it would appear that the process time can be shortened by 30 to 40%, depending on exactly when forced cooling is applied in the rolling schedule. The as-rolled microstructure is not affected very much by intermittent cooling between passes but prolonged exposure to water during the hold period causes the temperature of the surface layers of the plate to fall below A_{r3} . On resumption of rolling, this surface shell is reaustenitized by heat conduction from the interior of the plate; the surface austenite grain size is thereby considerably finer than that in the rest of the material, and this difference persists, of course, in the microstructure after rolling. Such nonuniformity of microstructure and properties in the through-thickness direction is hardly desirable, but it is unlikely to be directly detrimental to any particular bulk property of the plate (with the possible exception of bendability). Plates processed with shorter rolling times by the application of accelerated cooling between passes and/or under holding appear to exhibit equivalent strength and toughness properties to those controlled rolled in the conventional manner (Ref 11).

Normalizing. As with carbon steels, normalizing can be used to refine the ferrite-pearlite grain size in HSLA steels. However, because microalloyed HSLA steels may involve some strengthening by precipitation hardening, normalizing may cause a reduction in precipitation strengthening when stable carbonitride precipitates coarsen at typical austenitizing temperatures for normalizing. For example, normalizing a conventionally hot-rolled niobium steel reduces the yield strength considerably so that much of the precipitation strengthening increment that is due to niobium in the as-rolled condition is lost (Ref 23, 31). At the usual austenitizing temperatures for normalizing, most of the niobium has not been taken into solution and is present as relatively coarse precipitates. Thus, niobium inhibits grain coarsening, but provides little or no precipitation strengthening when the steel is normalized. However, the grain refining accounts for the improved low-temperature impact properties and most of the small increase in strength, compared to a niobium-free steel (Ref 23). Normalized niobium steels thus provide a fairly good combination of yield strength and ductile-brittle impact transition temperatures, even in semikilled steels (which contain free nitrogen that is detrimental to impact toughness). Niobium steels, along with titanium and vanadium steels, in the form of normalized, heavy-gage plate find important applications in offshore and general construction, shipbuilding, and pressure vessels in Europe. Normalized steels of this type are always fully aluminum killed (Ref 23). A typical example of a normalized niobium steel in the United States is the grade C steel in ASTM A 633 (Table 13). Minimum yield strengths of this steel range from 345 MPa (50 ksi) for plate thicknesses under 65 mm (2.5 in.) to 315 MPa (46 ksi) for plate thicknesses of 65 to 100 mm (2.5 to 4 in.). Charpy V-notch impact energies for the normalized steels in ASTM A 633 range from 41 J (30 ft · lbf) for transverse specimens at 0 °C (32 °F) to 20 J (15 ft · lbf) for transverse specimens at -50 °C (-60 °F).

Although normalized niobium steels have a finer ferrite grain size than do normalized carbon-manganese steels, when strength is of paramount importance, controlled rolling of niobium steels is preferred over normalizing because controlled rolling also provides a measure of precipitation strengthening. Vanadium, on the other hand, causes marked precipitation strengthening with limited grain refinement upon normalizing because practically all of the vanadium is in solution at usual normalizing temperatures. The strengthening with vanadium in normalized steels is far greater than can be obtained in normalized niobium steels (Ref 23). In the normalized condition, vanadium semikilled structural steels also have

impact properties superior to those of the semikilled niobium steels because vanadium combines with part of the nitrogen, thereby reducing the free-nitrogen content.

Table 14 lists some typical impact toughness values and yield strengths of aluminum-killed European vanadium steels in the normalized condition (see Table 15 for chemical compositions). In the United States, a typical example of a normalized vanadium steel is the grade E steel in ASTM A 633 (Table 13). Minimum yield strengths for this steel range from 415 MPa (60 ksi) for plate thicknesses under 100 mm (4 in.) to 380 MPa (55 ksi) for plate thicknesses of 100 to 150 mm (4 to 6 in.). Charpy V-notch impact energies are the same as for ASTM A 633, grade C, mentioned in the previous paragraph.

Precipitation Strengthening With Copper. Steels with about 0.6% or more copper can be precipitation strengthened by aging in a temperature range from about 425 to 650 °C (800 to 1200 °F). When reheated to 510 to 607 °C (950 to 1125 °F) after rolling, precipitation-hardened copper-bearing steels with more than 0.75% Cu have typical mechanical properties:

Tensile strength, MPa (ksi)	540 (78)
Yield strength, MPa (ksi)	485 (70)
Elongation in 50 mm (2 in.), %	20
Reduction of area, %	60

Mechanical Properties of Hot-Rolled HSLA Steels

The three major types of HSLA steel microstructures are dual-phase microstructures, acicular ferrite microstructures, and ferrite-pearlite microstructures. Typical tensile properties of dual-phase HSLA steels are summarized in Fig. 8 of this article and are discussed in more detail in the article "Dual-Phase Steels" in this Volume. Some limited yield strength and impact toughness values of various controlled-rolled acicular ferrite HSLA steels are given in Fig. 14.

Hot-rolled steels with ferrite-pearlite microstructures are the most common HSLA steels and are the primary focus of this section. Commercially available HSLA steels with ferrite-pearlite microstructures have yield strengths ranging up to 700 MPa (100 ksi), which is almost a fourfold increase over the 200 MPa (30 ksi) yield strength of conventional hot-rolled plain carbon steel. The increased strengths are developed by variations in composition and processing, but compositions having similar strengths are produced in different ways by different producers. There are three principal microalloying additions: niobium, vanadium, and titanium. Other additions can be made, depending on processing capabilities (particularly the cooling facilities) and on property requirements for the finished steel. In order to achieve good transverse properties, calcium-silicon ladle additions (or, less often, additions of rare-earth elements) are used in niobium- or vanadium-containing steels to control the shape of sulfide inclusions. For HSLA compositions containing titanium, ladle treatments for sulfide shape control are not required; titanium itself has the desired effect on the shape of sulfide inclusions. In recent years, calcium treatment has replaced rare-earth elements in sulfide inclusion shape control.

Tensile properties of some hot-rolled ferrite-pearlite HSLA steels are summarized in Tables 16 and 17. These properties are influenced by alloying elements and production methods.

(a) For compositions, available mill forms, and special characteristics of these steels, see Table 11.

(b) May vary with product size and mill form; for specific limits, refer to SAE J410.

(c) 0.2% offset.

(d) 180° bend test at room temperature. Used for mill acceptance purposes only; not to be used as a basis for specifying fabricating procedures.

In vanadium-microalloyed HSLA steels, yield strengths are influenced by manganese content (Table 12), nitrogen content (Fig. 17), and cooling rates (Fig. 11). The cooling rate, which determines the level of precipitation strengthening in vanadium steels, depends on the temperature, the product thickness, and the cooling medium. For thin products, temperature is the primary factor influencing cooling rates. For example, the strength of vanadium steel sheet is shown in Fig. 17 as a function of coiling temperature.

Fig. 17 Effect of coiling temperature and total nitrogen content on the yield strength of a vanadium microalloyed steel (0.13% C, 1.4% Mn, 0.5% Si, 0.12% V). Yield strengths are for a 6.3 mm (0.25 in.) thick sheet, finished at 900 °C (1650 °F) and then cooled at 17 °C/s (30 °F/s). Source: Ref 5

Yield strengths in niobium steels are also affected by rolling procedures and cooling rates. Figure 18 shows the effect of finishing temperature on the yield strength of a niobium-manganese steel after finish-rolling reductions of 75 and 66%. The range of yield strengths for controlled-rolled niobium steels of various compositions and section thicknesses is shown in Fig. 16. A typical controlled-rolled and accelerated-cooled HSLA steel is specified in ASTM A 841.

Fig. 18 Effect of finishing temperatures and reductions during finishing on the yield strength of a niobium-manganese steel (0.1% C, 1.25% Mn, 0.027% Nb, 0.2% Si, 0.03% Al). The reheat temperature was 1080 °C (1975 °F), with a cooling rate of 10 °C/s (18 °F/s) and a cooling temperature of 600 °C (1110 °F). Source: Ref 32

The notch toughness of microalloyed structural steels, as evaluated by Charpy-impact or drop-weight tests, is generally superior to that of structural carbon steels. The transition temperatures of the former also are lower. Figure 1 compares Charpy V-notch impact values for structural carbon steel (ASTM A 7), an HSLA steel, and a heat-treated constructional alloy steel. In the presence of a stress raiser, brittle failure is less likely to occur at subnormal temperatures in steels with lower transition temperatures. The transition temperatures of proprietary grades in the as-rolled or normalized conditions are controlled principally by chemical composition (particularly carbon) and ferrite grain size.

Notch toughness is reduced when the ferrite-pearlite HSLA steels are strengthened by precipitation hardening. The notch toughness of vanadium steels can be improved by normalizing or recrystallization controlled rolling. The notch toughness of niobium steels is normally improved by conventional controlled rolling, although the effects of recrystallization controlled rolling are under study. Figure 16 shows the range in notch toughness for controlled-rolled niobium steels, as evaluated by ductile-brittle transition temperatures.

Brittle Fracture. Most structural steels exhibit a transition in fracture behavior from ductile to brittle when the temperature is lowered to some critical temperature known as the nil-ductility transition temperature (NDTT). This temperature is defined as the temperature at which steel loses its ability to flow plastically in the presence of a sharp, cracklike discontinuity. At and below the NDTT, a brittle cleavage fracture will initiate from this discontinuity when stresses approaching the yield strength are reached in the volume of material surrounding the discontinuity. Once initiated, brittle fracture can propagate easily through regions of the structure that are subjected only to low levels of applied stress. In some steels, the transition from ductile to brittle fracture can occur at relatively high temperatures if a mechanical or metallurgical notch is present. If no sharp notch or crack is present, temperatures as low as -75°C (-100°F) are necessary to produce brittle fracture.

For welded structures, it is assumed that sharp notches are present; this makes brittle fracture at normal operating temperatures an important concern. Most structural members remain within elastic loadings, except for corners, cutouts, and similar locations where slight yielding may occur. For this type of service, brittle fracture is possible when certain conditions exist:

- The temperature is below the characteristic NDTT value for the steel being used
- A cracklike notch is present
- Load values are sufficiently large to raise the nominal stress level in the area of the notch to values close to or exceeding the yield strength

At and below the NDTT, the effects of residual stress may be considered. Weldments can contain residual stresses as high as 80% of the original yield strength. In these cases, an applied stress of only 20% of the yield strength would be sufficient to initiate brittle fracture. All three factors, high stress, low temperature, and cracklike flaws, must be present for brittle fracture to initiate. However, as flaw size increases, the stress required for crack initiation decreases. With larger flaw sizes, the levels can be well below the yield strength, and residual stresses will play an increasingly important role.

At temperatures slightly above or below the NDTT, localized plastic deformation is required to initiate brittle fracture, and residual stresses are less harmful. At temperatures well below the NDTT, design is critical; the nominal stress (the sum of applied stress and residual stress) must not exceed the yield strength at the locations of cracklike flaws. In general, the lower the temperature below NDTT, the less severe the notch must be to initiate brittle fracture. For very thin sections, stresses act in a manner that makes brittle fracture considerations less critical.

Each type of high-strength low-alloy steel has a range of NDTT values that depends on chemical composition, as-rolled ferritic grain size, and other variables; a range of 35°C (60°F) is not uncommon. On the basis of limited test data, expected NDTT ranges are estimated in Table 18. Grain coarsening may occur in different products because of rolling practice, which will increase the NDTT to above the maximum values shown in Table 18.

Table 18 Typical nil-ductility transition temperature ranges for several HSLA steels

Type of steel	Nil-ductility transition temperature	
	°C	°F
345 MPa (50 ksi) minimum yield strength; fully killed	-70 to -30	-90 to -25
345 and 550 MPa (50 and 80 ksi) minimum yield strength; fully killed; microalloyed, with low-carbon content and inclusion shape control	-70 to -30	-90 to -25
310 MPa (45 ksi) minimum yield strength; fully killed	-50 to -18	-60 to 0
310 MPa (45 ksi) minimum yield strength; silicon killed	-40 to -7	-40 to 20
290-450 MPa (42-65 ksi) minimum yield strength; semikilled	-25 to 10	-10 to 50

Directionality of Properties. In microalloyed HSLA steels, the changes in mechanical properties resulting from the use of niobium and vanadium, together with controlled rolling, result in improved yield strength, weldability, and toughness. The ferrite grain size is reduced, with an attendant increase in yield strength. Because of this increase, any reduction in toughness due to precipitation strengthening can generally be tolerated. The remaining properties, however, are typical only of samples tested in the direction of rolling. In the transverse direction, toughness is reduced considerably, and formability is inadequate because of the characteristic shape of nonmetallic inclusions which, during rolling, become elongated in the rolling direction. The effect of elongated inclusions on notch toughness is shown in Fig. 19. For the data presented, the impact energy for 100% shear fracture (upper-shelf energy) exceeds 55 J (40 ft · lbf) in the longitudinal direction, but is only 20 J (15 ft · lbf) in the transverse direction. For aluminum-killed steels, the low-shelf energy in the transverse direction is caused primarily by elongated sulfide inclusions. Reducing the sulfur content to 0.010% is not sufficient to eliminate directionality.

Fig. 19 Typical transition behavior for HSLA steel without inclusion shape control. Data determined on half-size

Charpy V-notch test specimens

To prevent the sulfides from becoming excessively elongated during hot rolling, it is necessary to alter their composition. This can be done by adding elements such as zirconium, titanium, calcium, or rare earths, which form sulfides having high melting points. Sulfides with high melting points are less plastic at hot rolling temperatures and cannot be deformed readily. As indicated in Fig. 20, rare-earth additions can effectively enhance transverse toughness so that when the cerium-to-sulfur ratio is between 1.5 and 2.0, the transverse upper-shelf energy approaches that of the longitudinal direction. Of the elements mentioned above, calcium and rare earths are the most frequently used for improving transverse or through-thickness properties.

Fig. 20 Effect of cerium-to-sulfur ratio on upper-shelf impact energy for HSLA steel. Circles, steel treated with mischmetal; squares, steel treated with rare-earth silicides

Fatigue Characteristics of HSLA Steels. Many structural applications for HSLA steels involve cyclic loading. The fatigue behavior of these steels therefore becomes important. In listing below, some of the fatigue characteristics of HSLA steels are compared to similar characteristics of hot-rolled low-carbon steels:

- HSLA steels have fatigue properties equivalent or superior to those of hot-rolled low-carbon steel. Microalloyed HSLA steels of the three major compositional approaches (vanadium, niobium, and titanium) have similar properties
- Although the notch sensitivity is somewhat greater, HSLA steels have greater notch fatigue resistance than hot-rolled low-carbon steels
- Large plastic prestrains tend to impair the fatigue life of both HSLA and hot-rolled low-carbon steels, particularly the response of HSLA steels to cyclic loading at high-strain amplitudes. Tensile prestrains are more detrimental to fatigue resistance than are compressive prestrains for both classes of material
- Most of the gains in monotonic strength achieved by work hardening are not retained under cyclic loading for either HSLA or hot-rolled low-carbon steel

Forming of HSLA Steels

High-strength low-alloy steels are generally formed at room temperature using conventional equipment. Cold forming should not be done at temperatures below 10 °C (50 °F). As a class, high-strength steels are inherently less formable than low-carbon steels because of their greater strength and lower ductility. This reduces their ability to distribute strain. The greater strength makes it necessary to use greater forming pressure and to allow for more springback compared to low-carbon steels. However, high-strength steels have good formability, and straight bends can be made to relatively tight

bend radii, especially with the grades having lower strengths and greater ductility. Further, high-strength steels can be stamped to relatively severe shapes such as automotive bumper facings, wheel spiders, and engine-mounting brackets. Table 19 ranks the formability of the various HSLA steels specified in SAE J410 (Table 11).

Table 19 Listing of SAE J410 grades in approximate order of decreasing toughness, formability, and weldability

Toughness	Formability	Weldability
945A	945A	945A
950A	950A	950A
950B	945C, 945X	950D
950D	950B, 950X, 942X	945X
945X, 950X	950D	950B, 950X
945C, 950C, 942X	950C	945C
955X	955X	955X, 950C, 942X
960X	960X	960X
965X	965X	965X
970X	970X	970X
980X	980X	980X

With the advent of inclusion shape control, cold formability has been substantially improved. Any grade produced with inclusion shape control can be more severely formed than a grade of the same strength level produced without inclusion shape control. Inclusion shape control enables the steel to be formed to nearly the same extent in both the longitudinal and transverse directions and is responsible for the moderately good formability of the higher-strength HSLA steels such as the grades having 550 MPa (80 ksi) yield strengths.

As with any metal, the bendability of HSLA steels is inversely proportional to strength and thickness, as shown by the suggested minimum bend radii in Table 20. These minimum bend radii are generally conservative, especially for inclusion shape controlled grades, as indicated by the bend test radii given in Table 21. The minimum radii in Table 20 represent safe production practice for parts made from HSLA steels without inclusion shape control; more liberal bend radii than those shown in Table 21 may be allowed for production of parts made from the inclusion shape controlled grades.

Table 20 Suggested minimum inside bend radii for SAE J410 steels of various strengths and thicknesses

Grade	Minimum bend radius for thickness of		
	<4.6 mm (0.180 in.)	4.6-6.4 mm (0.180-0.250 in.)	6.4-12.7 mm (0.250-0.500 in.)
942X	...	t	$2t$
945A, 945C	t	$2t$	$2.5t$
945X	t	t	$2t$
950A, 950B, 950C, 950D	t	$2t$	$3t$

965X	$3t$	$4t$	$4t$
970X	$3.5t$	$4.5t$	$4.5t$
980X^(a)	$3.5t$	$4.5t$	$4.5t$

(a) Available only in thicknesses to 9.5 mm (0.375 in.)

Table 21 Specified bend test radii for inclusion shape controlled ASTM A 715 steel sheet

Grade	Bend test radius for	
	Transverse bends ^(a)	Longitudinal bends ^(a)
50	$0.5t$	0
60	$0.5t$	0
70	$0.75t$	$0.5t$
80	$0.75t$	$0.5t$

(a) For sheet thicknesses up to 5.84 mm (0.2299 in.)

High-strength low-alloy steels can be hot formed. However, hot forming usually alters mechanical properties, and a particular problem that arises in many applications is that some of the more recent thermomechanical processing techniques (such as controlled rolling) used for plates in particular are not suitable where hot forming is used during fabrication. The kind of property deterioration obtained is shown in Fig. 21 for a thermomechanically treated steel. Similar effects can be predicted for accelerated-cooled steels. This problem can be circumvented by the use of a rolling finishing temperature that coincides with the hot-forming temperature (900 to 930 °C, or 1650 to 1700 °F). Subsequent hot forming therefore simply repeats this operation, and deterioration in properties is then small or even absent provided that grain growth does not occur.

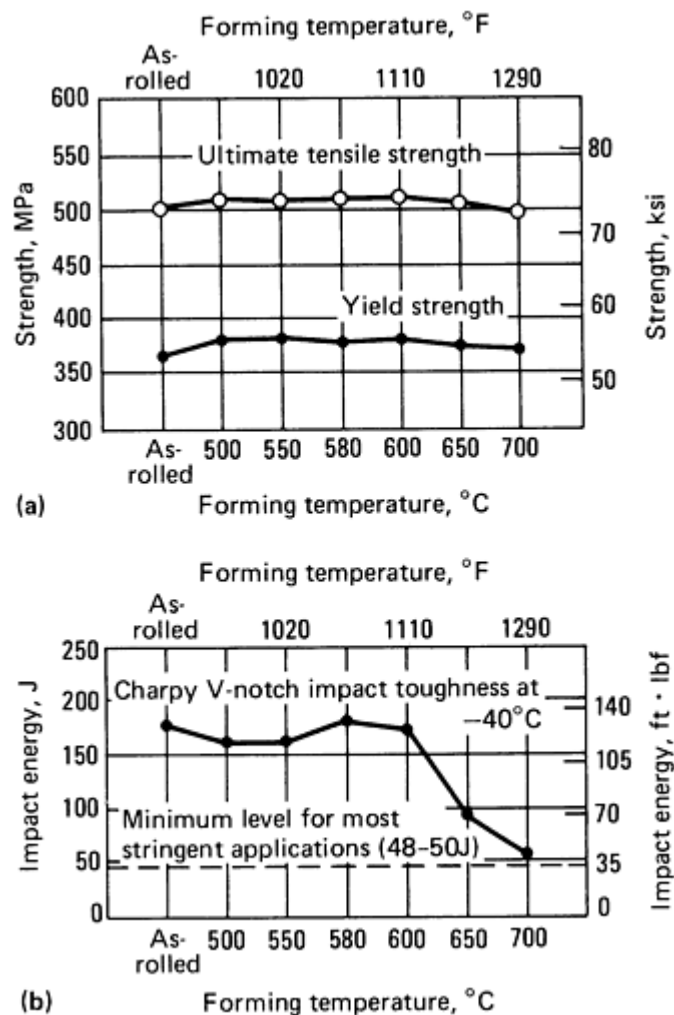

Fig. 21 Mechanical properties of a thermomechanically treated HSLA steel after reheating at different temperatures. (a) Yield and tensile strength. (b) Charpy V-notch impact toughness at -40 °C (-40 °F)

Producers should be consulted for recommendations of specific hot-forming temperatures and for comments on their effects on mechanical properties. According to one producer, satisfactory results can be obtained with certain grades by forming at temperatures between 815 and 900 °C (1500 and 1600 °F) without appreciable hardening after cooling. However, hot forming at these temperatures may result in material with mechanical properties equivalent to those of annealed or normalized material. Most producers advise against hot forming at temperatures below 650 °C (1200 °F). In the case of HSLA linepipe steels, hot bends are manufactured by induction heating followed by forming and (optional) quenching and tempering. The heating time is short (2 to 4 min), and limited grain growth occurs. Thus bending temperatures in the range of 850 to 1040 °C (1560 to 1900 °F) have been used successfully.

Welding of HSLA Steels

High-strength low-alloy steels are readily welded by any of the welding processes used for plain carbon structural steels, including shielded metal arc, submerged arc, flux-cored arc, gas metal arc, and electrical resistance methods. Welding can usually be performed without the need for preheat or postheat. Because the carbon content of HSLA steels is low, these steels exhibit hardening characteristics (in the HAZ) similar to those of plain carbon steels of similar low-carbon content. They do not exhibit the severe hardening in the HAZ that characterizes some plain carbon steels (those with sufficient carbon contents to attain yield and tensile strengths comparable to those of HSLA steels). Weldability generally decreases with increasing carbon content. For shielded metal arc welding, both mild steel covered electrodes and low-hydrogen electrodes can be used. Use of the latter is often recommended in order to preclude the need for preheating except when welding thick, highly restrained sections.

Submerged arc welding is often preferred because of the high production rates that can be attained. However, notch toughness of the weld metal in submerged arc welds can vary because of such factors as base metal composition, filler metal composition, type of welding flux, welding speed, current, voltage, and joint preparation. The choice of a particular steel is often greatly influenced by its ability to be used in welded construction, with less attention being given to the influence of steel composition on weld metal composition. In a submerged arc weld, the base metal may sometimes account for as much as 50 to 75% of the total weld metal. Base metal composition, therefore, can have an important effect on weld microstructure.

With constructional HSLA plate steels, the use of low-hydrogen electrodes and other precautions to minimize hydrogen pickup is advised. Various electrodes are available to match base metal strength and toughness. Preheating is generally required for all thicknesses over 25 mm (1 in.) and for highly restrained joints. Specific preheating temperatures depend largely on the grade, thickness, and welding process used and usually range from 40 to 200 °C (100 to 400 °F). Depending on design strength requirements for welded joints in heat-treated alloy grades, low-hydrogen electrodes E70 (485 MPa, or 70 ksi, minimum tensile strength) through E120 (830 MPa, or 120 ksi, minimum tensile strength) are used. In applications involving low stress levels (as when high-strength steel is used chiefly for its wear-resisting properties), E70 class electrodes are preferred. For joints requiring maximum strength, E120 class electrodes can be used. Electrodes containing vanadium must be avoided for any weldments that are to be subsequently stress relieved because reheating at temperatures below the critical temperature causes precipitation of vanadium carbides and raises the transition temperature of the weld metal.

The ductility and toughness of high-strength heat-treated steels depend on a tempered martensitic type of microstructure. Therefore, welding heat and preheat must be controlled so that the weld zone is cooled rapidly enough to retain a martensitic microstructure rather than the upper transformation products such as pearlite and ferrite that would result from unrestricted high-heat inputs and slow cooling. For this reason, the high heat usually generated by submerged arc and gas-shielded metal arc welding makes these processes unsuitable when maximum joint efficiency is required in high-strength heat-treated materials less than 13 mm ($\frac{1}{2}$ in.) thick. Many electrode-flux combinations have been developed to produce acceptable welds with a yield strength over 620 MPa (90 ksi) and an NDTT of about -100 °C (-150 °F) in both the as-welded and stress-relieved conditions. The best electrodes are based on either boron-molybdenum-titanium alloying or, more conventionally, nickel alloying.

Applications of HSLA Steels

High-strength low-alloy steels gained their first use as structural shapes and plates in the early 1960s because of their ability to be welded with ease. By the early 1970s, they were also used in pipelines in both elevated-temperature and severe arctic conditions. Later in the 1970s, concurrent with the energy crisis, another dominant application involved the use of HSLA steels to reduce the weight of parts and assemblies in automobiles and trucks. In the 1980s, bars, forgings, and castings have emerged as applications of particular interest. For example, weldable and nonweldable reinforcing bars are available, and high-strength forgings in the as-forged condition are being used to replace quenched and tempered steels. Shapes such as elbows and fittings for pipelines are also being cast out of microalloyed steel. A chronology of some of the important trends and developments in HSLA technology (as of 1984) is presented in Table 22.

Table 22 Chronology of trends and developments in HSLA steels

Period	Focus	Advances in technology
1939-1960	Discovery	Microalloying elements were used in a minor way in plate and in structural shapes to ensure the attainment of minimum yield strength
1960-1965	Research and experimentation on strengthening mechanisms	Development of a physical metallurgical basis. Hot-rolled semikilled or fully killed steels. Emphasis on replacing heat-treated steel
1965-1972	Toughening; experimentation on grain refinement and desulfurization	Hot-rolled steel, plate, pipeline steels, and structural shapes. Development of controlled rolling
1970-1976	Weldability; formability	Emphasis on lowering carbon and carbon equivalent, reduction of sulfur content, and control of inclusion shape. Improved bendability and stretchability
1972 to present	Secondary properties and steelmaking	Emphasis on brittle and ductile fracture control in pipelines and offshore structures, fatigue, resistance to H₂S corrosion, yielding behavior, formability of sheet steel, and development of continuous casting technology
1979 to present	Reformulation and reconstitution	Changes in availability of alloying elements such as molybdenum reawakened alloy developers. Previously inaccessible avenues opened by improvements in steelmaking. Focus on environmental degradation
1980 to present	Diffusion of technology	Cross-fertilization using development from other product areas
Future	Maturity; trend to higher strengths	Emphasis on reducing alloying costs and processing steps. Reconstitution of the steels to reflect direct hot-rolling and plate mill water-cooling technology

High-strength low-alloy steels are used in a wide variety of applications, and properties can be tailored to specific applications by the combination of composition and structures obtained in processing at the mill. For example, low-carbon and closely controlled carbon equivalent values provide good toughness and weldability. Good yield strength and fracture toughness are the products of fine grain size. The effects of microalloying elements (mainly niobium, vanadium, and titanium, but also aluminum and, to a lesser degree, nitrogen) are fully exploited by such mill finishing processes as controlled rolling and accelerated cooling. The scope of HSLA applications and different product forms used at the international level are implied by the production statistics for 1986 in Table 23. A more complete listing of structural applications includes bridges, buildings, electricity pylons, pressure vessels, penstocks, steel piling, railway tracks, trucks, trailers, earthmoving equipment, mining equipment, tanks, and reinforcing bars. The numbers in Table 23 show percentages of use in various applications by country. In some applications use by country varies markedly; in some instances, the explanation is found in local conditions or requirements. Japan, for example, is the major user of HSLA for shipbuilding, while Europe is the leader in plate and section applications in offshore construction for the harsh material requirements of oil and gas production platforms on the European continental shelf.

Table 23 Proportion of product forms made with HSLA steel (1986)

Product form	Proportion made with HSLA steel, %		
	Europe	North America	Japan
Linepipe	95	95	95
Shipbuilding	40	20	75
Offshore steels

Selection Guidelines. As a rule, it is necessary to look beyond comparative material costs to justify the use of HSLA steel. These steels almost always cost more than carbon steel and sometimes the alloy steel they compete with in a given application. High-strength low-alloy steels typically have an edge over other materials when their unique properties allow:

- Weight reductions
- New or more efficient designs with improved performance
- Attractive reductions in fabrication/ manufacturing costs
- Reduced transportation costs from weight reductions

These benefits may come in combinations, depending on the application. In automobiles, for example, the initial advantage in substituting an HSLA grade for a mild steel part is in weight reduction. The gage of the metal can be reduced because HSLA steel is stronger. This weight reduction not only provides improved gas mileage but can also have multiplying effects in the design when lightening one component leads to a series of weight reductions in associated parts and assemblies. In some situations, however, it is possible to justify the specification of HSLA steel on the basis of comparative material costs alone. The technique, called cost-effective weight reduction, is shown in Fig. 22. The replacement of a mild steel part with HSLA steel is said to be cost effective when full advantage can be taken of its higher strength. The amount of weight savings needed to make HSLA steel cost competitive in terms of material costs is indicated in Fig. 23. Data based on substituting a grade with a yield strength of 340 to 550 MPa (50 to 80 ksi) for a mild steel indicate that a savings in weight of about 30% is needed to reduce material costs. Of course, the savings in a given application depends on relative material costs.

Fig. 22 Material cost ratio as a function of weight reduction potential for various materials compared to mild steel as the base. Solid line is break-even line for materials cost.

Fig. 23 Weight savings required to break even when substituting 340 to 550 MPa (50 to 80 ksi) yield strength HSLA steels for mild steel

Another type of benefit involves the elimination of fabrication/manufacturing operations, such as those associated with the heat treating of quenched and tempered medium-carbon steels. For example, HSLA steels allow the production of high-strength forgings without any subsequent heat treatment (Fig. 24). By using a microalloyed steel in the as-forged condition, it is possible to eliminate quenching, tempering, straightening, and stress-relieving operations. In applications such as the forging of crankshafts or connecting rods, final savings in part costs of the order of 10% have been gained. Another example of reducing manufacturing steps with HSLA steel involves the production of cold-headed automotive fasteners (Fig. 25). Microalloyed steel wire rod replaced heat-treated medium-carbon wire. Benefits were realized before drawing and cold heading (elimination of spheroidize annealing) and after these operations (elimination of quenching and tempering).

Fig. 24 Required manufacturing steps for producing crankshafts from quenched and tempered and microalloyed medium-carbon steels

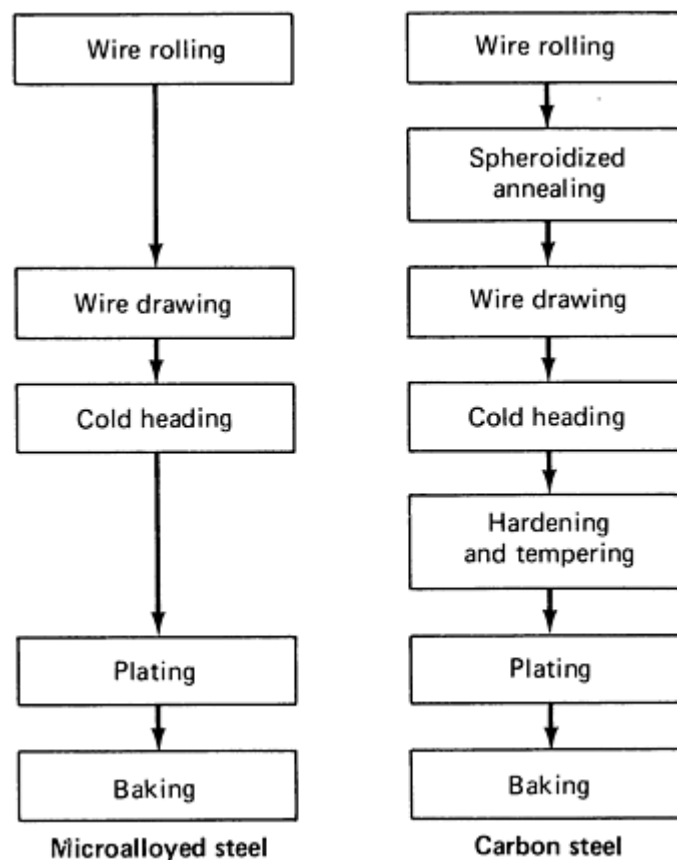

Fig. 25 Manufacturing sequence for class 8.8 automotive bolts from microalloyed and carbon steels

Other factors to consider in the selection of HSLA steel include:

- *Formability*: Limitations of microalloying technology in a given application may be overcome through part redesign and minor modifications in processing procedures

- *Notch toughness*: Microalloying in combination with controlled rolling generally provides better toughness properties than those of hot-rolled steel
- *Fatigue properties*: Adequate in most cases, with the possible exception being in the area of a welded joint
- *Weldability*: No longer considered a barrier to usage
- *Machinability*: At least similar and sometimes better than that of quenched and tempered steels. Control of alumina formation with calcium additions and substitutions of aluminum grain refinement by niobium have also been introduced. Free-machining grades (with added sulfur) are also available
- *Corrosion resistance*: Weathering HSLA steels can provide atmospheric-corrosion resistance four to eight times that of carbon steel, depending on the environment
- *Hydrogen-induced cracking and stress-corrosion cracking resistance*: Linepipe and pressure vessel steels have been developed with superior resistance to H₂S degradation

Oil and gas pipelines are a classic application of HSLA steel, and one of the first applications involved the use of acicular ferrite steel for pipelines in the Arctic Circle; see the section "Acicular Ferrite (Low-Carbon Bainite) Steels" in this article. The development of high-strength linepipe grades has permitted the use of large-diameter pipe operating at high pressure in excess of 11 MPa (1600 psi). Grades with minimum yield strengths up to 483 MPa (70 ksi) in thicknesses up to 25 mm (1 in.) are readily available. While tensile strength is a key requirement in linepipe, other properties are no less critical to the fabrication and operation of oil and gas pipelines. They include weldability, fracture toughness, and resistance to sour gas attack. In addition to higher strengths in greater thicknesses, HSLA steels can provide excellent toughness, good field weldability, resistance to ductile crack propagation, and, in some cases, resistance to sour gas and oil.

The girth weld is the main joining problem because it is a low heat input operation (HAZ cracking is not a problem at high welding temperature) that is carried out at high speed. The problem is alleviated by taking maximum advantage of the lowest possible carbon equivalent steels made possible by advanced thermomechanical rolling or accelerated cooling.

Fracture toughness is another major requirement. The approach to avoiding brittle fracture involves a combination of lower carbon content and fine grain size by microalloying along with thermomechanical rolling or accelerated cooling.

The common technique being used to prevent the propagation of ductile cracks through a gas pipeline is to lower sulfur content to less than 0.005%. Low sulfur content, in this instance about 0.002%, also reduces reactions with sour gas and oil transported in pipelines, and calcium treatment is used to ensure that residual sulfide inclusions are of the modified round type rather than the elongated type. Also important are the elimination of all other nonmetallic inclusions, particularly oxides, and the reduction or elimination of segregation by a combination of modified casting practices at the mill and a reduction in the content of the main segregating elements, carbon, manganese, and phosphorus.

Automotive Applications. High-strength low-alloy steels used by the United States automobile industry fall into four major groups:

- *Structural grades*: These materials are produced by a combination of phosphorus and microalloying elements (mainly niobium) to develop yield strengths between 255 and 345 MPa (37 and 50 ksi). They have a cost advantage over other HSLA grades with equivalent strength and are available in the hot- or cold-rolled condition. Drawing characteristics are rated superior to those of other HSLA steels
- *Formable grades*: Alloying elements commonly used to obtain high strength are niobium, vanadium, titanium, or zirconium. Transverse ductility is improved with zirconium, calcium, or rare-earth additions by changing the morphology of sulfide inclusions. Strength levels for automotive applications vary from 275 to 550 MPa (40 to 80 ksi). Fully killed grades are used most frequently, but semikilled grades are also used
- *Dual-phase grades*: These steels are used because of their superior formability over equivalent-strength microalloyed steels. Their duplex structure (ferrite and martensite) gives them a high strain hardening capability. Yield strengths range from 275 to 550 MPa (40 to 80 ksi)
- *Ultrahigh-strength grades*: In this instance, yield strengths of 550 MPa (80 ksi) are obtained by recovery-annealing cold-rolled HSLA grades. The most common strength levels used are 690, 825, and

965 MPa (100, 120, and 140 ksi). Low ductility has limited their applications

Experience in the application of cold- and hot-rolled HSLA sheet in automotive applications indicates the importance of additional requirements with respect of stiffness, crash behavior, fatigue life, corrosion resistance, acoustic properties, and, of course, formability and weldability. For one manufacturer (Ref 33), the substitution of HSLA for unalloyed steel requires a gage reduction of at least one-third to avoid an increase in manufacturing costs. This manufacturer (Opel in Germany), found certain limitations of HSLA sheet in automotive applications (Ref 33):

- Limited formability must be taken into consideration
- Fatigue strength of electric resistance welded joints is not much better than that of mild steel
- Increased notch sensitivity, which means higher cut edge sensitivity, must be taken into consideration
- With the use of thinner gages, reduced rigidity, susceptibility to corrosion, and noise behavior must be taken into consideration

The function of the automotive part is also important in determining whether or not the application of HSLA steels is feasible. For applications in which yield strength is the major consideration, as in door beams and bumper beams, the efficient use of HSLA can be made, and weight savings of 40 to 60% are possible when substituting, for example, higher-strength grades, such as 340 to 550 MPa (50 to 80 ksi) grades for mild steel. However, for other parts, such as outer body panels, which are also subjected to bending and/or buckling, stiffness is more important than yield strength. Part geometry and modulus of elasticity, the latter of which is the same for mild steel and HSLA steel, are the key factors. In such instances, an economic case cannot be made for using HSLA steel. However, through component redesign, such as adding beads or ribs to upgrade stiffness properties, the performance of the part may be improved and allow the efficient use of a higher-strength HSLA grade.

In addition to improvements in gas mileage through weight reduction, benefits may be found in increasing payloads without a change in fuel consumption. Candidate applications here include trucks, rail cars, off-highway vehicles, and ships. Ship applications of HSLA, however, are also limited by buckling and stiffness considerations.

Offshore Applications. The essential characteristics of steels for these applications include:

- Yield strength in the region of 350 to 415 MPa (50 to 60 ksi)
- Good weldability
- High resistance to lamellar tearing
- Lean composition to minimize preheating requirements
- High toughness in the weld heat-affected zone
- Good fracture toughness at the designated operating temperatures

Some of these goals have been realized through a reduction in impurities such as sulfur, nitrogen, and phosphorus in the steelmaking process for conventional steels. A major challenge, however, was to reduce carbon equivalents to improve weldability while still maintaining strength. This trend toward lower carbon equivalents and adequate strengths is shown in Table 24. Controlled rolling and accelerated cooling of niobium steels has also allowed reductions in carbon contents, which can be further reduced when accelerated cooling is employed.

Table 24 Comparison of typical 1972 and 1986 chemical composition of offshore structural steel

Element	Typical, 1972 ^(a)	Typical, 1986 ^(b)

(a) Minimum yield strength of 290 MPa (42 ksi).

(b) Minimum yield strength of 345 MPa (50 ksi).

(c) Carbon equivalent (CE) = $C + (Mn/6) + [(Cr + Mo + V)/5] + [(Ni + Cu)/15]$

Most offshore structures have been built using normalized carbon-manganese-niobium steel. Advances in computer control and rolling capability have led to the development of thermomechanically controlled processes that produce steels with higher strength, high fracture toughness, improved weldability, and lower cost. Thermomechanically controlled

processes combine controlled rolling and accelerated cooling (with controlled water sprays) or direct quenching to room temperature. Very fine-grain steel (ASTM grain size numbers 10 to 12) is produced. These steels are characterized by low-carbon content (usually less than 0.10% C), which makes them less susceptible to increases in hardness caused by rapid cooling rates between 425 to 260 °C (800 to 500 °F) during welding. Potentially, these steels can be welded with little or no preheat.

Two approaches have been taken to eliminate lamellar tearing. One is to reduce sulfur to levels below 0.008%, while the other involves modification of the sulfide shape. The latter relies on the addition of calcium or rare-earth metals to form spheroidal calcium or rare-earth sulfides. This approach usually results in both the elimination of lamellar tearing and an improvement in transverse impact properties. Both sulfur reduction and sulfide shape control are often used to eliminate lamellar tearing. Calcium treatment is preferred for sulfide inclusion shape control.

In using continuously cast steels, centerline segregation is also a concern. The approach favored by users is to minimize segregation through steelmaking practice and to minimize the use of elements (carbon, manganese, sulfur, and phosphorus) known to segregate easily during solidification. Soft, in-line reduction practices have been introduced. Users also specify minimum slab soaking time and temperature to control centerline segregation.

Cold-Forming Strip. The attraction of HSLA in this instance, particularly in automotive applications, is to make lighter parts by reducing gage requirements. Formability is a problem that is dealt with in several ways; welding is not as much of a problem with strip as it is with plate. Generally, welding problems are dealt with through the process itself or with surface treatments, rather than with modification of the fundamental characteristics of the steels themselves.

A tabulation of the cold-forming strip steels presently being used (along with their yield and tensile properties, ranges of carbon content, and alloying additions) are listed in Table 25. This tabulation includes the important category for interstitial-free steels, which have excellent deep-drawing characteristics (Fig. 8c).

Table 25 Cold-forming strip steels

Steel type	Processing	Range of minimum strength		Composition, %	
		Yield strength MPa (ksi)	Tensile strength MPa (ksi)	Carbon	Alloying element
Precipitation strengthened and grain refined	Hot rolled	280-600 (40-87)	400-700 (58-100)	0.05-0.15	1.5% Mn max plus Ti, Nb, or V
	Cold rolled	240-440 (35-64)	340-550 (49-80)	0.05-0.15	1.5% Mn max plus Ti, Nb, or V
Solid-solution strengthened	Hot or cold rolled C Mn	230-338 (33-49)	370-520 (54-75)	0.10-0.20	1.5% Mn max
	Cold rolled Al killed	220-300 (32-43)	340-435 (49-63)	<0.05	0.01% P
	Cold rolled,	220-300	300-400	<0.005	0.1% P plus Ti, Nb, or B

Bake hardening	Cold rolled Al killed	200-230 max (29-33 max)	310-380 (45-55)	0.01-0.02	0.1% max, possibly Si
		240-300 ^(a) (35-43) ^(a)			
	Cold rolled Nb	210 max (30 max)	360-380 (52-55)	<0.005	0.1% P plus Nb
		240 ^(a) (35) ^(a)			
Dual phase	Hot and cold rolled	200-900 (29-130)	350-1300 (50-190)	0.02-0.15	1.5% Mn
Transformation strengthened	Hot and cold rolled	1400 (200)	1500 (215)	0.20	Mn 1.5% Mn
Cold-work strengthened	Cold rolled	1000	1100	0.20	1.5% Mn, with Ti, Nb,

(a) After baking

The larger tonnage of cold-rolled steels have yield strengths less than 345 MPa (50 ksi). The microalloyed grades derive their higher yield strength from a combination of grain refinement and precipitation strengthening. They are normally produced in the hot-rolled or cold-rolled and annealed condition. Because of their limited formability, they are typically used for structures and reinforcement parts for automobiles, buildings, and various forms of domestic equipment. Forming properties are summarized in Table 26.

Table 26 Forming properties of various steel types

Primary strengthening mechanism	Stretchability	Drawability	Strength range
Cold worked	Very poor	Poor	Large
Recovery annealed	Poor	Poor	Large
Transformation strengthened	Moderate	Moderate	Large
HSLA precipitation grain refined	Moderate	Moderate	Fairly large
Solid-solution aluminum killed	Good	Good	Limited
Bake hardenable	Good	Good	Limited

Dual phase	Good	Moderate	Large
------------	------	----------	-------

Solid-solution strengthened grades have better formability than precipitation-strengthened grades. The most common alloying elements in this instance are manganese, silicon, and phosphorus. When phosphorus is above 0.10%, it tends to present problems in electric resistance welding. Solution-strengthened steels can be used in automotive body panels. These steels can be further strengthened by the addition of a small percentage of niobium (Table 25).

Bake-hardened grades are of interest because they are formed at a low strength level and subsequently strengthened during the paint-baking operation, at about 170 °C (340 °F). Advantage is taken of the quench aging mechanism. Carbon is quenched into solution at the cooling rates obtained after batch or continuous annealing and is later precipitated during the paint-baking operation.

Transformation-strengthened HSLA steels include dual-phase alloys in which the second phase may be martensite, bainite, or pearlite, depending on the strength requirements. These steels have good formability and weldability. They are used extensively in rolled form.

The highest strength strip with yield strengths up to 1600 MPa (230 ksi) are alloyed to ensure transformation to martensite. Applications include door impact beams and rear bumper supports. The formability of these grades is limited.

Corrosion protection is of concern because the corrosion resistance of nonweathering HSLA steel may not be significantly different from that of other steels. In this case, a number of coatings that inhibit corrosion and enhance the appearance of automobiles and buildings are available. They include zinc galvanized and aluminized coatings, which are applied by hot dip or continuous processes. A variety of colored organic coatings are available.

Structural Steels. Niobium, vanadium, and titanium microalloy additions are used, and chromium and molybdenum are added for elevated-temperature service. Processes used include controlled rolling, normalizing, quenching and tempering. For rolled shapes, direct accelerated cooling from the rolling temperature is a recent innovation. Steel frames for buildings are expected to be competitive with other building construction materials, including prestressed concrete. Benefits include an increase in the load bearing capacity of columns, weight savings, and gains in space. Composite construction (HSLA rolled sections and reinforcing bar bonded together with concrete) also appears to have potential. These composites offer great strength in compression, high building strength, and good resistance to fire.

Shipbuilding. Ship applications are limited by buckling and stiffness considerations. Growth in usage of hull plate is apparently held back by the fact that because HSLA and mild steel have the same elastic modulus, reducing thickness can lower elastic rigidity. This has caused concern regarding potential problems with hull rigidity.

One of the main challenges in this application area has been to reduce the need for welding preheat in the most common hull plate thicknesses. Some exceptions to this are reported. The Japanese are using readily welded hull structures employing HSLA grades that are processed by accelerated cooling and have yield strengths up to 400 MPa (58 ksi).

Crane and vehicle applications include trucks tankers, mobile cranes, dumper trucks, and heavy-duty material-handling equipment. Important properties include strength and toughness, resistance to brittle fracture, fatigue strength, weldability, and formability. In crane construction, high minimum yield strengths are needed to obtain high load-bearing capacities to handle dead loads. For example, a quenched and tempered grade with a minimum yield strength of 960 MPa (140 ksi) offers both technical and economic advantages, especially with cranes subjected to lifting heavy loads. Acceptable brittle fracture properties are obtained, for example, with acicular ferrite steel.

Resistance to cyclic loading is extremely important; in particular the fatigue strength of welded joints which is typically not as strong as that of the base metal because of microstructural changes due to the heat from welding. Improvements can be realized through postweld treatments. In using controlled rolled grades, heat input must be limited because of the likelihood of softening in the HAZ during welding.

Microalloyed HSLA steels used in commercial vehicles are typically cold formed. Good forming properties in the longitudinal and transverse directions are required when thermomechanically rolled steels are used. The desired result is obtained by optimizing sulfide shape control by the addition of calcium and cerium.

Railway Tank Car Applications. Three improved grades of high-strength steel for railway tank cars are defined by the ASTM specifications below. All the specified to a minimum yield strength of 345 MPa (50 ksi) and a tensile strength of 485 MPa (70 ksi).

- ASTM A 633D is a lower-carbon version of the presently used ASTM A 612 (TC-128B) steel (carbon-manganese steel with nickel, chromium, molybdenum, and vanadium additions). It is produced as a normalized grade
- ASTM A 737B (LC) is representative of the first generation of niobium microalloyed steels, which is produced as a normalized steel because equivalent properties cannot be developed by controlled rolling
- ASTM A 808 is representative of second-generation (controlled-rolled) niobium-vanadium microalloyed steels. For low-temperature service, sulfur should be limited to 0.010% (max)

These grades were compared by preliminary weldability analysis and fracture analysis (Ref 34). General conclusions indicate that:

- ASTM A 633D and A 737B (LC) are expected to satisfy near-term requirements, but they require postweld heat treatment to meet objectives
- ASTM A 808 (CR) with 0.010% (max) is expected to satisfy long-term requirements. Postweld heat treatment is not needed because a ductile HAZ is developed as-welded, a distinct advantage in making field repairs

Bars, forgings, and castings have emerged as the latest area of opportunity for microalloyed HSLA steels, and there has been rapid assimilation of the technology developed in other product areas. In particular, the search for higher strengths, elimination or reduction of heat treatments, simplified cold finishing or machining operations, and improved toughness have been combined with a simultaneous concern for other end-use properties such as toughness, machinability, and weldability. The result has been an integrated approach, including the proper selection of microstructure and transformation conditions, the application of thermomechanical processing and control of deoxidation and solidification practices (Ref 35).

The range of available steel types and compositions is indicated in Table 27. Carbon contents range from 0.05% in weldable castings and acicular ferrite bar used in cold heading to 0.60% for spring steels and high-strength wire. Tensile strengths range from 600 to 2000 MPa (87 to 290 ksi) and higher.

Table 27 Summary of microalloyed bar products, castings, and forgings

Steel product	Typical composition, %						Applications
	C	Mn	Si	Nb	V	Other	
Hot-rolled bar							
High carbon	0.58	0.80	0.30	0.04	Drawn wire having residual-deformation capability
Medium carbon							
Rebar	0.38	1.20	0.20	0.03 (or V)	Standard reinforcing bar

Structural	0.35	1.00	0.25	0.02-0.10	Machined automotive parts, or forged vanadium steel
Engineering	0.40	0.80	0.20	...	0.09 (or Nb)	...	Replaces quenched and tempered steel
Machined bar	0.30	1.20	0.30	0.03	...	Al free	Machined bar in automotive and engineering equipment
Low carbon	0.10-0.20	1.65	0.15	0.04	Weldable reinforcing bar, Arctic concrete structures, cryogenic storage tanks
Very low carbon	0.10	1.70	0	0.08	...	Boron	Cold-headed parts
Heat-treated bar							
Concast billets	0.25	1.30	0.20	0.03	Heat-treated parts for tractors, and so forth
Engineering	0.60	0.85	0.80	...	0.11	...	High-strength drawn wire
Rebar	0.18	0.60	0.05	...	0.05	...	Concrete structures
High carbon	0.58	0.85	2.10	0.15	0.12	...	
Forgings							
As-forged bar	0.30-0.40	0.80	0.20	...	0.09 (or Nb and 0.50 Cr)	...	Automotive components, universal couplings, stabilizer bars, wheel hubs, knuckle arms, connecting rods
Crankshafts	0.53	0.80	0.40	0.06 (or 0.10V)	Lightweight German automobiles
Small forgings	0.12	1.45	0.35	0.07	0.07 (or 0.015)	...	Automobile and off-highway equipment
Castings							
Nodes	0.15	1.40	0.30	0.03	0.07	0.48 CE max	Offshore platforms

Fittings	0.18	1.50	0.20	0.03	0.05	...	Pipeline elbows and fittings, and so on
Small castings	0.05	1.60	0.10	0.06	...	0.40 Mo	Small engineering castings, brake parts, compressors, and so on

Microalloying is used to satisfy a wide variety of metallurgical and manufacturing objectives, such as the substitution of as-rolled or as-forged steels for parts that required heat treatment for the improvement of toughness, fatigue behavior, machinability, or response to cold rolling. Examples of how microalloying is used in combination with processing to develop or improve specific properties follow.

Vanadium is generally used when it is necessary to develop hardening in conjunction with low austenitizing temperatures, but it is often necessary to add titanium, which prevents grain growth during high-temperature forging applications. For normal high-temperature rolling conditions, higher levels of precipitation strengthening in vanadium (and/or niobium) steels may have a detrimental effect on toughness. When controlled rolling is used in combination with niobium (0.03 to 0.08%) or extralow carbon content, toughness improved dramatically, and the properties of niobium steels are superior to those obtained in vanadium steels.

Niobium is added to improve the toughness of as-forged components. Such steels are widely used in Europe for automobile components. Niobium-containing steels are accepted for safety related parts such as steering knuckles and suspension components.

Niobium or vanadium are also added to hot-rolled carbon-manganese steel bars to effect grain refinement and improve toughness. Steel grades include 1020 through 1090. Niobium and/or vanadium are also added to the 4100 series for the same reason.

Medium- and Low-Carbon Microalloyed Bars. Vanadium and niobium act as precipitation strengtheners in medium-carbon (0.40%) steels are used widely in concrete-reinforcing bars. If enhanced toughness is needed for low-temperature service conditions or if weldability is a problem, carbon is reduced to the 0.10 to 0.20% range, maximizing the contribution of microalloying, rather than pearlite, in the strengthening process. Further improvements are available through controlled rolling.

However, low-carbon bainitic microalloyed steels appear to have better potential for replacing high strength-high toughness quenched and tempered steels than do medium-carbon microalloyed steels (Ref 36). Medium-carbon microalloyed steels are not ideal candidates for using the benefits of microalloying technology because their carbon contents and precipitation-strengthening effects contribute to poor notch toughness. Low-carbon steels microalloyed with ferrite-bainite microstructures exhibit a better combination of strength and toughness properties (Ref 36).

Solute niobium is used to eliminate the quenching and tempering of forged crankshafts (Table 27). Forging is followed by high-temperature (1225 °C, or 2240 °F) induction heating and controlled air cooling, which results in a desirable microstructure consisting of 80% pearlite and 20% ferrite.

Microalloying of carbon-manganese steel bars can increase the strength of steel bars (0.35 to 0.45% C) used to reinforce concrete. Recent applications call for improvements in bendability, weldability, and toughness for low ambient service temperatures or for low-temperature structures, such as refrigerated warehouses, liquid natural gas storage facilities, foundations for nuclear power stations, and construction in seismic-prone areas. For these conditions, carbon content is lowered, and the strengthening properties of niobium and vanadium are used singly or in combination.

Microalloying elements as a substitute for aluminum in grain refinement can facilitate the production of desired inclusion compositions for applications in which machining or surface treatments such as carburizing or nitriding are involved. Such steels are designed to decrease the abrasive tool wear caused by hard alumina inclusions. Deoxidation practice produces soft, glassy inclusions that are relatively plastic at hot working temperatures. The elimination of aluminum requires the use of another strong deoxidant such as calcium and the addition of niobium or other suitable grain refiner.

Niobium or vanadium containing castings have applications that are given in Table 27. Large castings, for example, are used in offshore construction. Built-in reinforcements improve performance under cyclic loading conditions. Many low-carbon steels have inherently high ductility and can tolerate the presence of some potentially injurious second-phase particles such as carbide eutectics. Niobium and niobium-vanadium microalloyed low-carbon steels with manganese and molybdenum have been developed and applied in Europe. Castings are used in either the as-cast or as-quenched and tempered condition. In either case, weldability is reported to be excellent. A development for the future are low-carbon (0.02%) manganese-niobium-boron-titanium steels, originally developed as high heat input filler (weld) metals.

Cold-Rolled HSLA Steel. Although most HSLA steel is hot rolled, large tonnages of cold-rolled HSLA sheet and strip are produced. However, because many applications of cold-rolled steel already involve thin product forms, substituting a thinner, stronger steel for weight savings may not be feasible because of stiffness and deflection considerations.

The general types of cold-rolled HSLA steels utilize precipitation strengthening, solid-solution strengthening, or strengthening from a dual-phase (martensite in ferrite) microstructure. These types of cold-rolled HSLA steel are compared in Fig. 8(b) in terms of ductility and tensile strength. the cold-rolled solution-hardened steels have superior elongation and stretchability compared with cold-rolled precipitation-strengthened steels of the same tensile strength, but are limited to a tensile strength of about 600 MPa (87 ksi). The cold-rolled precipitation-strengthened steels allow higher tensile strengths compared with solution-strengthened steels, but these have less ductility at a given tensile strength (Fig. 8b). Because titanium provides sulfide shape control and precipitation strengthening, titanium steels have plastic-strain ratios up to 1.4 at tensile strengths of 550 to 650 MPa (80 to 95 ksi) (Ref 23).

Dual-phase steels offer improved ductility at higher tensile strengths (Fig. 8b). Sheets of dual-phase steel have very low yield strengths without sharp yield points (that is, continuous yielding), but the yield strengths are increased substantially during forming or by a tempering or aging treatment at 300 to 400 °C (570 to 750 °F) for about 5 min after air cooling. The formability (in terms of plastic-strain ratios and strain-hardening exponents) of a dual-phase steel is compared with other cold-rolled automotive sheet steels in Table 28 and Fig. 8(c). Although many of the high-strength cold-rolled steels have rather low plastic-strain ratios and, hence, are not deep drawn as readily, their drawability can be improved by a suitable precoating lubricant (Ref 23, 37). Interstitial-free steels offer the best deep-drawing properties (Fig. 8c).

Table 28 Mechanical properties of cold-rolled, high-strength steels

Steel grade	Yield strength		Tensile strength		Elongation, %	Formability factors	
	MPa	ksi	MPa	ksi		Strain-hardening exponent (n)	Plastic-strain ratio (r)
Low carbon, killed	172	25	275	40	40	0.23	1.4
Structural grade, high strength	275	40	380	55	35	0.22	1.4
Formable grade, high strength	345	50	415	60	30	0.20	1.1
	550	80	620	90	18	0.14	0.8
Dual phase, high strength	345	50	550	80	25	0.24	0.8
Ultrahigh strength	825	120	860	125	8

	965	140	1000	145	4
--	-----	-----	------	-----	---	-----	-----

Selection and Application Example. The following describes the use of structural and HSLA steels in an architectural application.

Example: Design and Construction of Retractable SkyDome Roof.

Toronto, Canada's SkyDome, completed in June 1989, is a multipurpose structure that seats 54,000 for baseball, 55,000 for football, and up to 70,000 for special events (Ref 38). The SkyDome incorporates a patented rigid frame structural steel retractable roof. Within a span of 20 min, the movable roof transforms the SkyDome from an open-air stadium into an enclosed air-conditioned or heated domed stadium.

Roof Dimensions. The roof consists of four panels, three of which are movable, that stack and interlock on top of each other to provide a closed, sealed, and weather-tight structure (Fig. 26). Utilization of four parabolic arch panels in this arrangement exposes 91% of the seats in the open-air section and stacks all four panels within the building footprint (Ref 39). The roof covers 32,275 m² (347,420 ft², or 8 acres); it rises to a maximum height of 86 m (282 ft), which is high enough to accommodate a 31-story skyscraper within its confines. The roof has a steel dead weight of 69,000 kN (7760 tonf) (Ref 39, 40). The movable panels have the following dimensions:

Panel	Depth		Span	
	m	ft	m	ft
1	50	165	175	575
2	50	165	206	675
3	50	165	190	625

Fig. 26 Location and progressive movement of the three movable roof panels of the SkyDome as it is converted from an open-air facility into an enclosed environmentally controlled dome. (a) All four panels stacked at the north end of the SkyDome in the open position. Panel 4 remains stationary. (b) Panel 1 is first to move as it begins its circular motion. (c) All three movable panels are in motion as panels 2 and 3 begin their straight-line motion while panel 1 continues in its circular path. (d) Within 20 min, panel movement is complete and the structure is in its closed position. Source: Adapted from *Sports Illustrated*, 12 June 1989

Roof Opening Procedure (Ref 41). The roof of the SkyDome is closed most of the time. Panel 4 is fixed in place at the north end and has the configuration of a segment of a spherical shell or quarterdome. Panel 1 has a similar shape but is slightly larger. When the roof is in the closed position, panel 1 is located at the south end, directly opposite panel 4. As the roof opens, panel 1 travels along a 310 m (1020 ft) circular 4-rail track, carried by 22 steel-wheeled bogies (10 of which are fitted with two 7.5-kW, or 10-hp, dc electric-drive units), and parks itself directly above panel 4. Some of these roof-carrying bogies weigh up to 36 tonnes (40 tons) per unit.

Panels 2 and 3 sit adjacent to each other when the roof is closed. A total of 16 bogies are used to move panels 2 and 3. Eight of the bogies on panel 2 and six of the bogies on panel 3 are equipped with drive units. Panel 2 is slightly higher and larger than panel 3. Both move linearly northward when the roof is opening. Panel 2 initially moves along the parallel tracks and passes directly over panel 3, which then also starts its travel to the north end of the stadium.

All three movable panels are simultaneously in motion for a short portion of the 20-min operation when panel 1 begins its journey around the circular track. Panel 1 eventually comes to rest approximately 180° from its original position. When the SkyDome roof is open, panel 1 nests above the similarly shaped panel 4 but below panel 3, while panel 2 sits atop the other three panels (Fig. 26).

Structural Components. Figure 27 shows the SkyDome in its final stages of construction. Construction of the geometrically complex SkyDome roof involved the fabrication and erection of 7575 tonnes (8330 tons) of structural steel components, 975 tonnes (1070 tons) of bogies, and 930 tonnes (1025 tons) of rails, all to a high degree of precision (Ref 41).

Fig. 27 SkyDome construction nearing completion. Courtesy of Jane Welowszky, SkyDome Stadium Corporation of Ontario

The 7575 tonnes (8330 tons) of zinc-coated structural steels used in the roof structure are employed in a linear system of parallel arches with transverse trusses of hollow structural steel (HSS). These HSS trusses conform to Canadian Standards Association (CSA) specification CAN 3-G40.21-M81, which closely approximates ASTM A 572. CSA grade 300 W is equivalent to ASTM grade 42, while CSA grade 300 W is equivalent to ASTM grade 50. CSA type W steels are suitable for general welded construction where notch toughness at low temperatures is not a design requirement (Ref 42).

Grade 300 W, with a minimum yield strength of 300 MPa (44 ksi), is a standard general-purpose weldable hot-rolled structural steel with 130 to 170 HB hardness. In addition to being used for the joint connections and plates in the structural framework of the SkyDome, grade 300 W structural plate was used extensively in the construction of the bogies that move the roof panels.

Grade 350 W, with a minimum yield strength of 350 MPa (50 ksi), is a cold-rolled and stress-relieved HSLA weldable structural steel with 130 to 180 HB hardness. Grade 350 W structural steel was seam welded to form a hollow square tube which serves as a roof tubular support. These HSS square tubes range in size from 150×150 mm (6×6 in.), with a thickness of 6.4 mm, to 300×300 mm (12×12 in.), with a thickness of 12 mm. The use of standard structural steel hollow tubes has resulted in a roof that has great strength and stiffness characteristics and yet is relatively lightweight and has a depth relative to the large span, which is close to 206 m (675 ft) wide.

Trusses for the four panels were shop-fabricated in large sections and then bolted on-site using 140,000 ASTM A 325 galvanized 25 mm (1 in.) diam bolts and corresponding ASTM A 194 nuts. Both fastener types were made from quenched and tempered medium-carbon high-strength structural steels.

Acoustic Roof Deck. The actual roof covering consists of an acoustic steel roof deck weighing 500 tonnes (550 tons). The galvanized corrugated square-profile steel panels conform to ASTM A 446 grades B (255 MPa, or 37 ksi, minimum yield strength; 310 MPa, or 45 ksi, minimum tensile strength) and C (275 MPa, or 40 ksi, minimum yield strength; 380 MPa or 55 ksi minimum tensile strength); (Ref 42). The thickness of the steel strip and sheet used to fabricate the panels varies from 0.813 to 1.27 mm (0.032 to 0.050 in.) depending on location and load requirements.

The corrugated panels are fluted, perforated (Fig. 28), and provided with interlocking J-hook ends (Fig. 29) to provide a baffle that contains crowd noise within the confines of the structure when it is closed. Fabricated in lengths up to 6 m (20 ft), the corrugated panels have square profiles of 450 mm (18 in.) or 600 mm (24 in.). Both the inner and the outer exposed sections of the corrugated panels contain acoustic pads to absorb sound (Fig. 30). In addition, the roof sandwich also includes thermal insulation and a 1 mm (0.04 in.) thick single-ply polyvinyl chloride membrane.

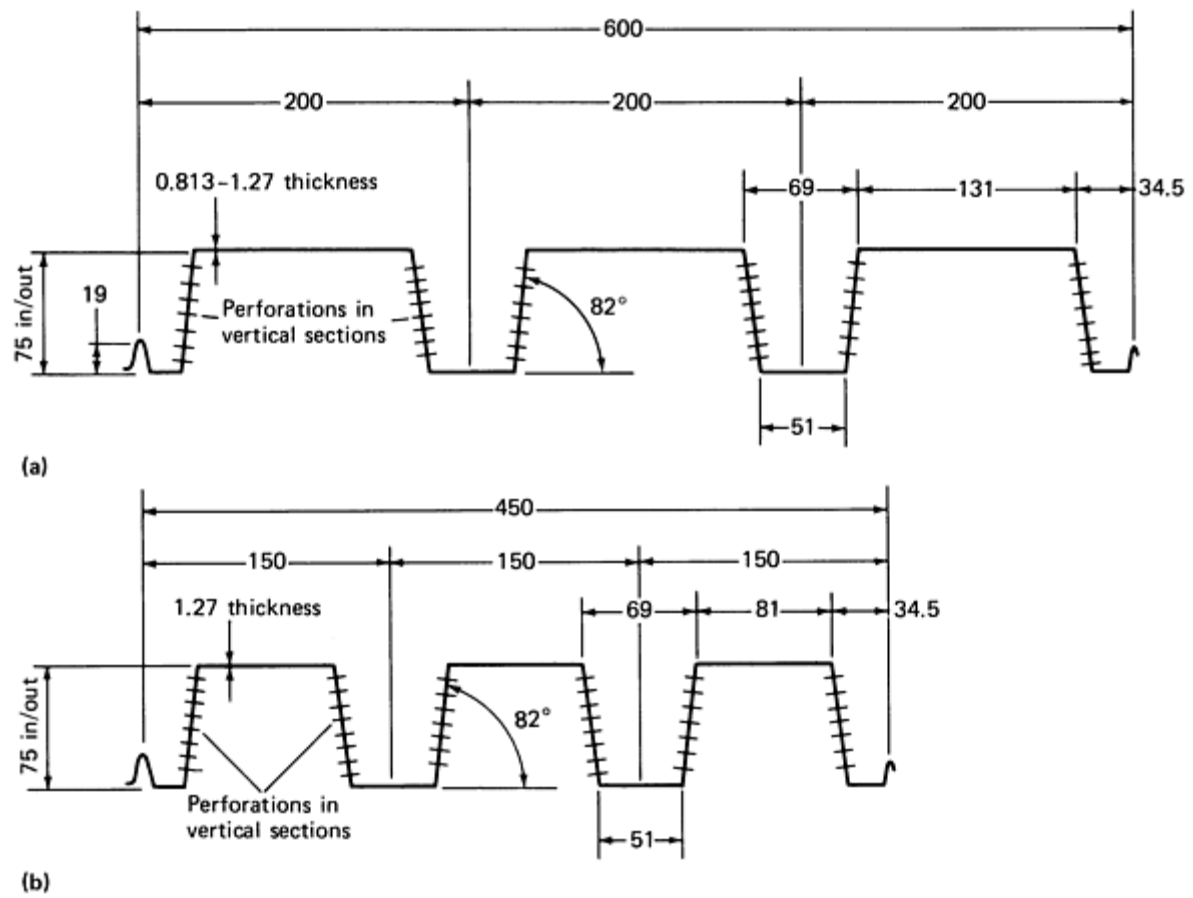

Fig. 28 Profiles of the fluted and perforated interlocking galvanized steel corrugated roof panels. All dimensions are given in millimeters. (a) D-200 roof panel, 600 mm (24 in.) wide coverage. (b) D-150 roof panel, 450 mm (18 in.) wide coverage

Dual-Phase Steels

G.R. Speich, Department of Metallurgical Engineering, Illinois Institute of Technology

Introduction

DUAL-PHASE STEELS are a new class of high-strength low alloy (HSLA) steels. This class is characterized by a tensile strength value of approximately 550 MPa (80 ksi) and by a microstructure consisting of about 20% hard martensite particles dispersed in a soft ductile ferrite matrix. The term dual phase refers to the predominance in the microstructure of two phases, ferrite and martensite (Fig. 1). However, small amounts of other phases, such as bainite, pearlite, or retained austenite, may also be present.

Fig. 1 Ferrite-martensite microstructure of a dual-phase steel (0.06% C, 1.5% Mn; water quenched from 760 °C, or 1400 °F). Source: Ref 1

In addition to high tensile strength, other unique properties of these steels include continuous yielding behavior, a low 0.2% offset yield strength, and a higher total elongation than other HSLA steels of similar strength.

Although limited research on dual-phase steels began in the early 1970s (Ref 2), an intense interest in these steels commenced with work done in 1975 and 1976. A 1975 study showed that continuous annealing in the intercritical temperature range produced steels with a ferrite-martensite microstructure (similar to that shown in Fig. 1) and a ductility superior to that of normal precipitation-hardened or solid solution hardened HSLA sheet steels (Ref 3). Some of these results are shown in Fig. 2 and in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume. A 1976 study showed that intercritical heat treatment of vanadium-nitrogen HSLA steels resulted in a large increase in ductility at a strength level of 550 MPa (80 ksi)(Fig. 3). This study also showed that the increased ductility was accompanied by an increased formability of automotive parts (Ref 4). Prior to this time, steels with a strength of 550 MPa (80 ksi) that were produced without intercritical heat treatment were considered to have poor formability.

Fig. 2 Relation between tensile strength and total elongation for various HSLA sheet steels. Source: Ref 3

Fig. 3 Stress-strain curves for the HSLA sheet steels SAE 50X and SAE 80X (with yield strengths of 340 and 550 MPa, or 50 and 80 ksi, respectively) and a dual-phase steel (with a yield strength of 550 MPa, or 80 ksi). Source: Ref 4

Large-scale efforts were begun at this time in many steel research laboratories to develop new steel compositions as well as alternative processing procedures for producing large tonnages of dual-phase steels. It was predicted that in the 1980s automobile manufacturers would need the large tonnages to produce more fuel-efficient cars. Gasoline mileage requirements were mandated by the government because of the gasoline shortage; it was expected that using thinner sheets of high-strength dual-phase steels for automobile bodies would save weight and enable the cars to meet these requirements. Much of this work has been reported in several review papers (Ref 1, 5, 6). Pertinent aspects of dual-phase steels, such as heat treatment, microstructures, mechanical properties, and new advances are discussed in this article.

Typical chemical compositions of present day dual-phase steels are given in Table 1. In general, these steels have a carbon content of less than 0.1%, which ensures that they can be spot welded. The carbon content also produces about 20% of the martensite in the microstructure after intercritical annealing and rapid cooling. Manganese in amounts of 1 to 1.5% is added to ensure sufficient hardenability so that martensite is formed upon rapid cooling. Chromium and

molybdenum have also been added in amounts that are usually under 0.6%. Silicon is added to provide solid solution hardening. Small amounts of microalloying additions, such as vanadium, niobium, and titanium, may be added to provide precipitation hardening and/or grain size control. Nitrogen may be added to intensify the precipitation-hardening effects of vanadium.

Table 1 Typical dual-phase steel compositions

Production method	Composition, wt %						
	C	Mn	Si	Cr	Mo	V	N
Continuous annealing, hot-rolled gage	0.11	1.43	0.61	0.12	0.08	0.06	0.01
Continuous annealing, cold-rolled gage	0.11	1.20	0.40
Box annealing	0.12	2.10	1.40

Dual-Phase Steels

G.R. Speich, Department of Metallurgical Engineering, Illinois Institute of Technology

Heat Treatment of Dual-Phase Steels

Annealing Techniques and Steel Compositions. Dual-phase steels can be produced by intercritical heat treatment with either continuous annealing or box annealing techniques. In continuous annealing, the steel sheet is heated for a short time (30 s) in the intercritical temperature range to form ferrite-austenite mixtures. This is followed by accelerated cooling (6 °C/s, or 10 °F/s) to transform the ferrite-austenite mixtures into ferrite-martensite mixtures (Fig. 4). The actual cooling rate depends on sheet thickness and the quenching conditions on a given annealing line.

Fig. 4 Formation of austenite in 0.06C-1.5Mn steel from preexisting pearlite after short-time annealing in the intercritical temperature range (30 s at 740 °C, or 1365 °F). M, Martensite (austenite at intercritical temperature); P, pearlite (dissolution only partly complete). Source: Ref 7

Box annealing is similar to continuous annealing, but the heating times are much longer (3 h), and the cooling rates are much slower (10 °C/h, or 20 °F/h). Because of its slow cooling rates, box annealing requires steels with much higher alloy contents than does continuous annealing (Table 1). To achieve desired hardenability with box annealing, 2.5% Mn steels that can at times contain appreciable amounts of silicon and chromium have been proposed.

Formation of Austenite During Intercritical Annealing. The formation of austenite during intercritical annealing can be separated into several steps (Ref 7). The first is almost instantaneous nucleation of austenite at pearlite or grain boundary cementite particles, followed by rapid growth of austenite until the carbide or pearlite is dissolved. The next step is the slower growth of austenite into ferrite at a rate that is controlled by carbon diffusion in austenite at high temperatures (850 °C, or 1560 °F) and by manganese diffusion in ferrite (or along grain boundaries) at low temperatures (750 °C, or 1380 °F). Finally, there is a very slow equilibration of ferrite and austenite at a rate that is controlled by manganese diffusion in austenite, under conditions of very long time annealing at low temperatures.

An example of austenite formation in a 0.06C-1.5Mn steel after short-time annealing at 740 °C (1365 °F) is shown in Fig. 4. The kinetics of austenite formation at different temperatures in a 0.12C-1.5Mn steel are summarized in Fig. 5, with the time and controlling kinetic mechanism for each of the various steps indicated at each temperature.

Fig. 5 Kinetics of austenite formation in 0.12C-1.5Mn steel. Source: Ref 7

Transformation of Austenite After Intercritical Annealing. Although the transformation of austenite after intercritical annealing is similar to the transformation of austenite after regular annealing, several features make the former process unique. First, because the carbon content of the austenite, C_γ , is fixed by the intercritical annealing temperature (Fig. 6), the hardenability of the austenite varies with this temperature. Second, because the martensite forms by a diffusionless transformation, the martensite phase inherits the carbon content of the austenite, which is much higher than that of the original steel C_0 . Finally, because it is important to maintain the necessary carbon balance, using the lever rule will indicate that the amount of the austenite will vary with the intercritical temperature and the original carbon content of the steel (Fig. 7).

Fig. 7 Percentage of austenite formed at various intercritical temperatures for 1.5% Mn steels containing 0.005 to 0.12% C (paraequilibrium conditions). Source: Ref 8

Upon water quenching at high cooling rates from the intercritical annealing temperature, practically all of the austenite transforms to martensite that has the classical high-carbon martensite substructure (Fig. 8). At slower cooling rates, such as in hot-oil quenching, some retained austenite remains in the form of very small particles (Fig. 9). This austenite is stable upon cooling to room temperature or subzero temperatures but transforms upon plastic straining (Fig. 10).

Changes in the Ferrite Phase During Intercritical Annealing. Because the ferrite is in contact with the austenite at the intercritical temperature, upon cooling from this temperature it may grow epitaxially into the austenite as part of the transformation mechanism (Ref 12). In cold-rolled steels, recrystallization of the ferrite occurs rapidly and is generally complete before the steel reaches the intercritical temperature, even during the rapid heating encountered on most continuous annealing lines (Ref 12). Changes in the carbon content of the ferrite may occur during intercritical annealing. These changes arise from several different causes. First, the solubility of carbon in the ferrite may be lower at the intercritical temperature than it is in the as-received material. Second, the carbon content of the ferrite may decrease because of the increased alloy content. For example, the addition of 1.5% Mn under equilibrium conditions would lower the solubility of carbon at 740 °C (1365 °F) from 0.02 to 0.005%, as shown by the isothermal section of the iron-manganese-carbon phase diagram in Fig. 11. Additions of silicon are also reported to lower the carbon content of the

ferrite (Ref 14). Variations in the cooling rate from the intercritical temperature can also affect the carbon content of the ferrite phase because of the precipitation of cementite from the ferrite.

Mechanical Properties of Dual-Phase Steels

Work Hardening and Yield Behavior. In general, ferrite-martensite steels do not show a yield point. The combination of high residual stresses and a high mobile dislocation density in the ferrite causes plastic flow to occur easily at low plastic strains (Ref 12). As a result, yielding occurs at many sites throughout the ferrite, and discontinuous yielding is suppressed (Fig. 3).

The work-hardening process in dual-phase steels can be separated into three stages (Ref 12). In the first stage (0.1 to 0.5% strain), rapid work hardening takes place because of the elimination of residual stresses and the rapid buildup of back stresses caused by the plastic incompatibility of the two phases. In the second stage (0.5 to 4% strain), transformation of retained austenite occurs. Finally, in the third stage (4 to 18% strain), dislocation cell structures are formed, and further deformation in the ferrite is governed both by dynamic recovery and cross slip and by eventual yielding of the martensite.

The work-hardening behavior of dual-phase steels is thus very complex, especially in the initial stages. However, the high initial work-hardening rate is believed to contribute to the good formability of these steels, compared to other HSLA steels of a similar strength level (Ref 4). Also, the lack of a yield point in these steels eliminates Lüders band formation and ensures that a good surface finish is obtained after forming.

Yield and Tensile Strength. Based on simple composite-strengthening theory, the strength of dual-phase steels should be expected to increase when either the volume fraction or strength (hardness) of the martensite phase is increased (Fig. 12). Actual data for 1.5% Mn steels support this idea (Fig. 13). In addition, the strength of the mixture increases as the strength of the ferrite or matrix phase increases. As already stated, the strength of the martensite which depends primarily on the carbon content of the phase, is determined by the intercritical annealing conditions and the original carbon content of the steel. The strength of the ferrite phase depends on the grain size and solid solution hardening contributions of the alloying elements. A complete discussion of the factors controlling the strength of dual-phase steels requires the use of more sophisticated models and continuum mechanics.

Solid data points indicate tensile strength values converted from hardness values. $S_{Y,0,M}$, yield strength intercept of martensite; C , ratio of the yield strength of martensite to the yield strength of ferrite. Source: Ref 15

Ductility. The enhanced ductility of dual-phase steels has been attributed to many causes, including the lower carbon content of the ferrite, the plasticity of the martensite phase, the amount of epitaxial ferrite, and the amount of retained austenite. A single cause for the enhanced ductility of dual-phase steels has not yet been isolated. Of these factors, however, the amount of retained austenite and the manner in which it transforms upon plastic straining has gained more acceptance as an explanation than the others. In cases where the amount of retained austenite is increased by controlling the annealing cycle, ductility has been found to reach a maximum value (Fig. 14).

Tempering and Strain Aging. Tempering of water-quenched dual-phase sheet steels can also be done during subsequent hot dip galvanizing operations or during paint-baking cycles, although in the latter case the part has been

plastically strained, and the tempering actually represents a strain-aging process. In-line tempering may be used in commercial continuously annealed sheet to prevent changes in properties upon subsequent tempering.

Such tempering involves a combination of effects expected for tempering of each of the individual phases. Thus, in the high-carbon martensite phase, recovery of the defect structure, precipitation of carbides, and transformation of retained austenite are expected. Similarly, in the ferrite phase, both carbon segregation to dislocations and precipitation of carbides are expected. In addition, there are synergistic effects that arise from the presence of both phases, such as the generation of residual stresses and a high dislocation density in the ferrite. Therefore, carbon segregation to the dislocations and the elimination of the residual stresses by the volume contraction of the ferrite are important parts of the tempering process. At temperatures near 200 °C (390 °F), the segregation of carbon to the dislocations and the elimination of residual stresses results in an increase in yield strength and a return of discontinuous yielding, but only if the martensite content is below 30% (Fig. 15).

Fig. 15 Effect of tempering 1 h at 200 °C (390 °F) on the stress-strain behavior of 0.06 and 0.20% C steels containing 1.5% Mn with variation percentages of martensite. Source: Ref 15

In general, dual-phase steels are nonaging at room temperature (Ref 16), and they exhibit sluggish aging behavior at temperatures up to 270 °C (520 °F). However, deformation caused either by cold rolling or by tensile straining accelerates the aging process. One study has suggested that the more rapid strain aging by tensile straining is a result of making the dislocation density more uniform than that which is present in the temper-rolled condition (Ref 16). As a result, the diffusion distance for carbon is reduced, and carbon diffusion is faster. Figure 16 shows the effect of aging at 170 °C (340 °F) after temper rolling and tensile straining on the return of the yield point in the absence of strain.

Dual-Phase Steels

G.R. Speich, Department of Metallurgical Engineering, Illinois Institute of Technology

New Advances in Dual-Phase Steels

Prior dual-phase steel developments have been focused primarily on applications involving cold- or hot-rolled sheet containing about 0.1% C. Carbon content was kept low because of the need for good spot weldability. More recent developments have been directed at producing dual-phase steels with higher carbon contents (0.2 to 0.4% C) for use in forging or bar applications (Ref 17, 18). Although such steels cannot be easily welded because of their high levels of carbon, they are suitable for forging or bar applications where spot welding is not required and where mechanical fastening is possible. A typical chemical composition of such steels is 0.40% C, 1.49% Si, 0.84% Mn, 0.005% P, 0.006% S, 0.035% Al, and 0.0024% N (total). In addition to a higher carbon content these steels also have a higher silicon content.

These newer high-carbon dual-phase steels have a unique combination of total elongation and tensile strength (Fig. 17). By increasing the carbon content, the tensile strength of the steel is increased up to 1040 MPa (150 ksi), yet the total elongation remains constant at 30%. This unusually good combination of tensile strength and total elongation is superior to that which can be obtained with conventional steels; it is associated with the high amounts of retained austenite, which vary from 10 to 20% as the carbon content is increased (Fig. 17). Producing such large amounts of austenite in these steels involves intercritical annealing followed by isothermal transformation in the bainite temperature range (Fig. 18). The high silicon content of these steel results in the displacement of almost all the carbon into the austenite and the suppression of cementite formation. As a result, the carbon content of the austenite at the isothermal transformation temperature is increased. This results in the stabilization of the austenite at room temperature, and ductility is enhanced because of the transformation of the metastable austenite upon plastic straining.

Ultrahigh-Strength Steels

Revised by Thoni V. Philip, TVP Inc.; and Thomas J. McCaffrey, Carpenter Steel Division of Carpenter Technology Corporation

Introduction

STRUCTURAL STEELS with very high strength levels are often referred to as ultrahigh-strength steels. The designation ultrahigh-strength is arbitrary because no universally accepted strength level for the term has been established. Also, as structural steels with greater and greater strength have been developed, the strength range for which the term is applied has gradually increased. This article describes those commercial structural steels capable of a minimum yield strength of 1380 MPa (200 ksi).

In addition to the steels discussed in this article, many other proprietary and standard steels are used for essentially the same types of applications, but at strength levels slightly below the arbitrary, lower limit of 1380 MPa (200 ksi) established above for the ultrahigh-strength class of constructional steels. Medium-alloy steels such as 4330V and 4335V (vanadium-modified versions of the corresponding AISI standard steels) are among the more widely used steels for yield strengths of 1240 to 1380 MPa (180 to 200 ksi). Certain proprietary steels such as Hy Tuf (a silicon-modified steel similar to 300M) exhibit excellent toughness at strengths up to or slightly above 1380 MPa. The toughness of Hy Tuf is about the same as a maraging steel in this strength range. For properties and other information on steels and strength ranges not discussed here, the reader is referred to sources such as *Aerospace Structural Metals Handbook* (Ref 1) and to producer data sheets.

The ultrahigh-strength class of constructional steels is quite broad and includes several distinctly different families of steels. This article covers only medium-carbon low-alloy steels, medium-alloy air-hardening steels, and high fracture toughness steels. It does not cover 18Ni maraging steels, which are described in the article "Maraging Steels" in this Volume. Ultrahigh-strength steels of the stainless type (martensitic, martensitic precipitation hardenable, semiaustenitic precipitation hardenable, and cold-rolled austenitic steels) are covered in the Section "Specialty Steels and Heat-Resistant Alloys" in this Volume.

The effects of thermomechanical treatments such as ausforming and hot-cold working on the properties of many ultrahigh-strength steels have been investigated extensively. With adequate deformation while the steel is in a metastable condition, strength levels not attainable by standard quench and temper treatments have been obtained, quite often with higher ductility and fracture toughness than those normally expected at these very high strength levels. However, such thermomechanical treatments are not widely used commercially, presumably because of practical difficulties in adapting experimental techniques to actual production. Therefore, thermomechanical treatments and the properties that result from them are also excluded from this article.

Ultrahigh-Strength Steels

Revised by Thoni V. Philip, TVP Inc.; and Thomas J. McCaffrey, Carpenter Steel Division of Carpenter Technology Corporation

Medium-Carbon Low-Alloy Steels

The medium-carbon low-alloy family of ultrahigh-strength steels includes AISI/SAE 4130, the higher-strength 4140, and the deeper hardening, higher-strength 4340. Several modifications of the basic 4340 steel have been developed. In one modification (300M), silicon content is increased to prevent embrittlement when the steel is tempered at the low temperatures required for very high strength. In AMS 6434, vanadium is added as a grain refiner to increase toughness, and the carbon is slightly reduced to promote weldability. Ladish D-6ac contains the grain refiner vanadium; slightly higher carbon, chromium, and molybdenum than 4340; and slightly lower nickel. Other less widely used steels that may be included in this family are 6150 and 8640. Chemical compositions are given in Table 1.

Table 1 Compositions of the ultrahigh-strength steels described in text

Designation or trade name	Composition, wt % ^(a)

(a) P and S contents may vary with steelmaking practice. Usually, these steels contain no more than 0.035 P and 0.040 S.

(b) AF1410 is specified to have 0.008P and 0.005S composition. Ranges utilized by some producers are narrower.

(c) 9Ni-4Co steels and premium quality, vacuum arc remelted steels typically is specified to have 0.10 max P and 0.10 max S. Ranges utilized by some producers are narrower.

No new or distinctly different commercial steels have been added to this class of steels in recent years. Rather, developmental efforts have been primarily aimed at increasing ductility and toughness by improving melting and processing techniques and by using stricter process control and inspection. Steels with fewer and smaller nonmetallic inclusions and mill products with fewer internal and surface imperfections are produced by the use of selected raw materials as the melting charge and the employment of advanced melting techniques such as vacuum carbon deoxidation, vacuum degassing, electroslag remelting (ESR), vacuum arc remelting (VAR), and double vacuum melting (vacuum induction melting followed by vacuum arc remelting). These techniques yield less variation in properties from heat to heat and lot to lot; greater ductility and toughness, especially in the transverse direction; and greater in-service reliability.

Medium-carbon low-alloy ultrahigh-strength steels are readily hot forged, usually at temperatures ranging from 1065 to 1230 °C (1950 to 2250 °F). Specific forging temperatures are described in the subsequent sections for the various steels. To avoid stress cracks resulting from air hardening, the forged part should be slowly cooled in a furnace or embedded in lime, ashes, or other insulating material. Prior to machining, the usual practice is to normalize at 870 to 925 °C (1600 to 1700 °F) and temper at 650 to 675 °C (1200 to 1250 °F), or to anneal by furnace cooling from 815 to 845 °C (1500 to 1550 °F) to about 540 °C (1000 °F) if the steel is a deep air-hardening grade. These treatments impart moderately hard structures consisting of medium-to-fine pearlite. In this condition, the steel has a machinability rating of about one-half that of B1112. A very soft structure consisting of spheroidized carbides in a matrix of ferrite can be obtained by full annealing. Such a structure is not as well suited for machining as a normalized structure: The steel tends to tear, chips break away with difficulty, and metal tends to build up on the machining tool. However, the soft and ductile spheroidized structure is preferred for severe cold-forming operations such as spinning and deep drawing.

Medium-carbon low-alloy steels are cut, sheared, punched, and cold formed in the annealed condition. Cutting is commonly done with a saw or abrasive disk; if these steels are flame cut, most of them are preheated to about 315 °C (600 °F). After flame cutting, because the cut edge is hard, blanks are annealed before being formed or machined.

Preferably, medium-carbon low-alloy steels are welded in the annealed or normalized condition and then heat treated to the desired strength. Such processes as inert-gas tungsten-arc, shielded metal-arc, inert-gas metal-arc, and pressure processes, as well as flash welding, can be used. Filler wire having the same composition as the base metal is preferred, but if such is not available, the filler wire should at least be of a composition that will produce a deposit that responds to heat treatment in approximately the same manner as the base metal. To avoid brittleness and cracking, preheating and interpass heating are used, and complex structures are stress relieved or hardened and tempered immediately after welding.

4130 Steel

AISI/SAE 4130 is a water-hardening alloy steel of low-to-intermediate hardenability. It retains good tensile, fatigue, and impact properties up to about 370 °C (700 °F); however, it has poor impact properties at cryogenic temperatures. This steel is not subject to temper embrittlement and can be nitrided. It usually is forged at 1100 to 1200 °C (2000 to 2200 °F); finishing temperature should never fall below 980 °C (1800 °F).

Available as billet, bar, rod, forgings, sheet, plate, tubing, and castings, 4130 steel is used to make automotive connecting rods, engine mounting lugs, shafts, fittings, bushings, gears, bolts, axles, gas cylinders, airframe components, hydraulic lines, and nitrided machinery parts.

Heat Treatments. The standard heat treatments that apply to 4130 steel are:

- *Normalize:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold for a time period that depends on section thickness; air cool. Tempering at 480 °C (900 °F) or above is often done after normalizing to increase yield strength
- *Anneal:* Heat to 830 to 860 °C (1525 to 1575 °F) and hold for a time period that depends on section thickness or furnace load; furnace cool
- *Harden:* Heat to 845 to 870 °C (1550 to 1600 °F) and hold, then water quench; or heat to 860 to 885 °C (1575 to 1625 °F); hold and then oil quench. Holding time depends on section thickness
- *Temper:* Hold at least $\frac{1}{2}$ h at 200 to 700 °C (400 to 1300 °F); air cool or water quench. Tempering temperature and time at temperature depend mainly on desired hardness or strength level
- *Spheroidize:* Heat to 760 to 775 °C (1400 to 1425 °F) and hold 6 to 12 h; cool slowly

Properties. Table 2 summarizes the typical properties obtained by tempering water-quenched and oil-quenched 4130 steel bars at various temperatures. Because 4130 steel has low hardenability, section thickness must be considered when heat treating to high strength (see Table 3).

4140 Steel

AISI/SAE 4140 is similar in composition to 4130 except for a higher carbon content. It is used in applications requiring a combination of moderate hardenability and good strength and toughness, but in which service conditions are only moderately severe. Because of its higher carbon content, 4140 steel has greater hardenability and strength than does 4130, but with some sacrifice in formability and weldability. Tensile strengths of up to 1650 MPa (240 ksi) are readily achieved in 4140 through conventional quench and temper heat treatments. This steel can be used at temperatures as high as 480 °C (900 °F), above which its strength decreases rapidly with increasing temperature. The material can be readily nitrided. Like other martensitic and ferritic steels, 4140 undergoes a transition from ductile to brittle behavior at low temperatures, the transition temperature varying with heat treatment and stress concentration. When 4140 is heat treated to high strength levels, it is subject to hydrogen embrittlement, such as that resulting from acid pickling or from cadmium or chromium electroplating. Ductility can be restored by baking for 2 to 4 h at 190 °C (375 °F).

The forging of 4140 steel can be done readily, usually at 1100 to 1200 °C (2000 to 2200 °F); the finishing temperature should not be below 980 °C (1800 °F). Parts should be cooled slowly after hot forming. This steel has good weldability using any of the standard welding methods. For welding, preheating at 150 to 260 °C (300 to 500 °F) and postheating at 600 to 675 °C (1100 to 1250 °F), followed by slow cooling, are recommended. Cold drawn 4140 has a machinability rating of 62% (B1112, 100%).

The steel 4140 is available as bar, rod, forgings, sheet, plate, strip, and castings. It is used for many high-strength machine parts (some of them nitrided) such as connecting rods, crankshafts, steering knuckles, axles, oil well drilling bits, piston rods, pump parts, high-pressure tubing, large industrial gears, flanges, collets, machine tool parts, wrenches, tong jaws, sprockets, and studs.

Heat Treatments. The standard heat treatments that apply to 4140 steel are:

- *Normalize:* Heat to 845 to 900 °C (1550 to 1650 °F) and hold for a time period that depends on section thickness; air cool
- *Anneal:* Heat to 845 to 870 °C (1550 to 1600 °F) and hold for a time period that depends on section thickness of furnace load; furnace cool
- *Harden:* Heat to 830 to 870 °C (1525 to 1600 °F) and hold; then oil quench. (For water quenching, which is rarely used, hardening temperatures are 815 to 845 °C, or 1500 to 1550 °F.) Holding time depends on section thickness
- *Temper:* Hold at least $\frac{1}{2}$ h at 175 to 230 °C (350 to 450 °F) or 370 to 675 °C (700 to 1250 °F); air cool or water quench. Tempering temperature and time at temperature depend mainly on desired hardness. To avoid blue brittleness, 4140 is usually not tempered between 230 and 370 °C (450 and 700 °F); 4140 is not subject to temper embrittlement
- *Spheroidize:* Heat to 760 to 775 °C (1400 to 1425 °F) and hold 6 to 12 h; cool slowly

Properties. Table 4 summarizes the mechanical properties obtained by tempering oil-quenched 4140 steel at various temperatures. Because 4140 is not a deep-hardening steel, section size should be considered when specifying heat treatment, especially for high strength levels. The effects of mass on hardness and tensile properties are given in Table 5. As expected, 4140 steel has low impact strength at cryogenic temperatures.

4340 Steel

AISI/SAE 4340 steel is considered the standard by which other ultrahigh-strength steels are compared. It combines deep hardenability with high ductility, toughness, and strength. It has high fatigue and creep resistance. It is often used where severe service conditions exist and where high strength in heavy sections is required. In thin sections, this steel is air hardening; in practice, it is usually oil quenched. It is especially immune to temper embrittlement. It does not soften readily at elevated temperatures; that is, it exhibits good retention of strength. Hydrogen embrittlement is a problem for

4340 heat treated to tensile strengths greater than about 1400 MPa (200 ksi). Parts exposed to hydrogen, such as during pickling and plating, should be baked subsequently. This steel exhibits extremely poor resistance to stress-corrosion cracking when tempered to tensile strengths of 1500 to 1950 MPa (220 to 280 ksi). It can be readily nitrided, which often improves fatigue life.

The 4340 steel is usually forged at 1065 to 1230 °C (1950 to 2250 °F); after forging, parts may be air cooled in a dry place or, preferably, furnace cooled. The machinability rating of 4340 is 55% for cold-drawn material, and 45% for annealed material (cold-rolled B1112, 100%). A partly spheroidized structure obtained by normalizing and then tempering at 650 °C (1200 °F) is best of optimum machinability. The 4340 steel has good welding characteristics. It can be readily gas or arc welded, but welding rods of the same composition should be used. Because 4340 is air hardening, welded parts should be either annealed or normalized and tempered shortly after welding.

The steel 4340 is widely and readily available as billet, bar, rod, forgings, sheet, tubing, and welding wire. It is also produced as light plate and castings. Typical applications include bolts, screws, and other fasteners; gears, pinions, shafts, and similar machinery components; crankshafts and piston rods for engines; and landing gear and other critical structural members for aircraft.

Heat Treatments. The standard heat treatments that apply to 4340 steel are:

- *Normalize*: Heat to 845 to 900 °C (1550 to 1650 °F) and hold for a time period that depends on section thickness; air cool
- *Anneal*: Heat to 830 to 860 °C (1525 to 1575 °F) and hold for a time period that depends on section thickness or furnace load; furnace cool
- *Harden*: Heat to 800 to 845 °C (1475 to 1550 °F) and hold 15 min for each 25 mm (1 in.) of thickness (15 min, minimum); oil quench to below 65 °C (150 °F), or quench in fused salt at 200 to 210 °C (390 to 410 °F), hold 10 min, and then air cool to below 65 °C (150 °F)
- *Temper*: Hold at least $\frac{1}{2}$ h at 200 to 650 °C (400 to 1200 °F); air cool. Temperature and time at temperature depend mainly on desired final hardness
- *Spheroidize*: The preferred schedule is to preheat to 690 °C (1275 °F) and hold 2 h, increase the temperature to 745 °C (1375 °F) and hold 2 h, cool to 650 °C (1200 °F) and hold 6 h, furnace cool to about 600 °C (1100 °F), and finally air cool to room temperature. An alternative schedule is to heat to 730 to 745 °C (1350 to 1375 °F), hold several hours, and then furnace cool to room temperature
- *Stress relieve*: After straightening, forming, or machining, parts may be stress relieved at 650 to 675 °C (1200 to 1250 °F)
- *Bake*: To avoid hydrogen embrittlement, plated parts must be baked at least 8 h at 185 to 195 °C (365 to 385 °F) as soon after plating as possible

Properties. Through-hardening of 4340 steel can be done by oil quenching, for round sections up to 75 mm (3 in.) in diameter, and by water quenching, for larger sections (up to the limit of hardenability). The influence of section size on tensile properties of oil-quenched and water-quenched 4340 is indicated in Table 6.

Table 6 Effects of mass on the mechanical properties of 4340 steel

Consumable electrode vacuum melting (commonly known as vacuum arc remelting, or VAR) and electroslag remelting (ESR) have resulted in substantial improvements in the properties of 4340 steel because of significant reductions in gas content and in the size and number of nonmetallic inclusions. Typical average gas contents of air-melted 4340 are 1.4 ppm H₂, 25 ppm O₂, and 100 ppm N₂; these can be reduced to about 0.9 ppm H₂, 4 ppm O₂, and 53 ppm N₂ by vacuum arc remelting. the remelted steels are more homogeneous than are the air-melted products. Table 9 compares average transverse tensile properties obtained on several heats of air melted and vacuum arc remelted 4340 steel tempered to different strength levels. Longitudinal and transverse mechanical properties, including R.R. Moore fatigue data and plane-strain fracture toughness data, or air-melted and vacuum arc remelted 4340 are compared in Table 10. Mechanical properties are significantly improved by VAR processing, especially in the transverse direction, although for plane-strain fracture toughness there appear to be no significant differences between longitudinal and transverse values for the same heat. Table 11 compares longitudinal properties of VAR- and ESR-processed 4340 bars. No significant differences in properties between VAR and ESR steels are evident; the two processes appear to give roughly equivalent improvements over air melting.

Table 9 Transverse tensile properties of air-melted and vacuum arc remelted 4340 steels

Properties listed are averages of several heats from the same producer; billet size and amount of hot reduction were not available.

300M Steel

Alloy 300M is basically a silicon-modified (1.6% Si) 4340 steel, but it has slightly higher carbon and molybdenum contents and also contains vanadium. This steel exhibits deep hardenability and has ductility and toughness at tensile strengths of 1860 to 2070 MPa (270 to 300 ksi). Many of the properties of this steel are similar to those of 4340 steel, except that the increased silicon content provides deeper hardenability, increased solid-solution strengthening, and better resistance to softening at elevated temperatures. Compared to 4340 of similar strength, 300M can be tempered at a higher temperature, which provides greater relief of quenching stresses. The so-called 260 °C (500 °F) embrittlement is displaced to higher temperatures. Because of the high silicon and molybdenum contents, 300M is particularly prone to decarburization. During thermal processing, care should be exercised to avoid decarburization, or the decarburized layer should be removed after processing. When heat treated to strength levels higher than 1380 MPa (200 ksi), 300M is susceptible to hydrogen embrittlement. If the steel is properly baked after plating, the resulting improvement in properties is better than that for 4340 or D-6ac steel of equal strength.

The steel 300M is forged at 1065 to 1095 °C (1950 to 2000 °F). Forging should not be continued below 925 °C (1700 °F). After forging, it is preferred that parts be slowly cooled in a furnace, but they may be allowed to cool in air in a dry place. Although 300M can be readily gas or arc welded, welding is generally not recommended; welding rod of the same composition should be used. Because 300M is an air-hardening steel, parts should be either annealed or normalized and tempered after welding. The machinability rating of annealed 300M is about 45% (B1112, 100%). A partially spheroidized structure, obtained by normalizing and then tempering at 650 to 675 °C (1200 to 1250 °F), gives optimum machinability.

Typical applications of 300M, which is available as bar, sheet, plate, wire, tubing, forgings, and castings, are aircraft landing gear, airframe parts, fasteners, and pressure vessels.

Heat Treatments. The standard heat treatments that apply to 300M steel are:

- *Normalize:* Heat to 915 to 940 °C (1675 to 1725 °F) and hold for a time period that depends on section thickness; air cool. If normalizing to enhance machinability, charge into a tempering furnace at 650 to 675 °C (1200 to 1250 °F) before the steel reaches room temperature
- *Harden:* Austenitize at 860 to 885 °C (1575 to 1625 °F). Oil quench to below 70 °C (160 °F) or quench in salt at 200 to 210 °C (390 to 410 °F), hold 10 min, and then air cool to 70 °C (160 °F) or below
- *Temper:* Hold at 2 to 4 h at 260 to 315 °C (500 to 600 °F). Double tempering is recommended. This tempering procedure produces the best combination of high yield strength and high impact properties. Tempering outside this temperature range results in severe deterioration of properties
- *Spheroidize:* Heat to about 775 °C (1430 °F) and hold for a time period that depends on section

thickness or furnace load. Cool to 650 °C (1200 °F) at a rate no faster than 5.5 °C/h (10 °F/h); then cool to 480 °C (900 °F) no faster than 10 °C/h (20 °F/h); finally, air cool to room temperature. The same schedule is recommended for annealing

Properties. Variations in hardness and mechanical properties of 300M with tempering temperature are presented in Table 12. Because 300M has deep hardenability, heat-treated bars 75 mm (3 in.) in diameter have essentially the same tensile properties as do bars 25 mm (1 in.) in diameter. Reductions in tensile ductility and impact strength, however, are observed in heat-treated bars 145 mm ($5\frac{3}{4}$ in.) in diameter. Variations in properties of 300M (including impact strength at room and low temperatures) with section size are presented in Table 13.

Table 12 Typical mechanical properties of 300M steel

In R.R. Moore fatigue tests of polished specimens, endurance limits of about 800 MPa (116 ksi) and 585 MPa (85 ksi) were found for longitudinal and transverse specimens, respectively, of air-melted 300M heat treated to a tensile strength of about 2025 MPa (294 ksi) by oil quenching from 870 °C (1600 °F) and tempering at 290 °C (550 °F). Vacuum arc remelting and electroslog remelting improve transverse ductility and impact strength by producing a cleaner microstructure. Transverse tensile properties of air-melted and vacuum arc remelted 300M are compared in Table 14. The data are average values from several heats.

Table 14 Transverse tensile properties of air-melted and vacuum arc remelted 300M steel

Tempering temperature		Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Reduction in area, %
°C	°F	MPa	ksi	MPa	ksi		
Air melted							
315	600	1960	284	1620	235	5.0	11
425	800	1760	255	1540	223	7.0	14
540	1000	1585	230	1480	215	9.0	22
Vacuum arc remelted							
260	500	2020	293	1620	235	7.0	25
425	800	1760	255	1550	225	10.0	34

In another study, transverse tensile properties were determined for specimens of 300M taken from 40 billets, each 125 mm (5 in.) square, representing seven vacuum arc remelted heats. Specimens were normalized for 1 h at 925 °C (1700 °F), reheated 1 h at 870 °C (1600 °F), oil quenched, and tempered 4 h at 315 °C (600 °F). Average properties were as follows: tensile strength, 1978 MPa (286.9 ksi); yield strength, 1671 MPa (242.4 ksi); elongation, 9.3%; and reduction in area, 36.6%. Property ranges were: tensile strength, 1896 to 2039 MPa (275.0 to 295.7 ksi); yield strength, 1581 to 1752 MPa (229.3 to 254.1 ksi); elongation, 9 to 10%; and reduction in area, 31.7 to 45.0%.

Samples from two heats of VAR 300M steel heat treated to an average tensile strength of 2025 MPa (294 ksi), average yield strength of 1710 MPa (248 ksi), average elongation of 11.5%, average reduction in area of 45.6%, and average Charpy V-notch impact value of 27 J (20 ft · lbf) showed an average K_{Ic} value of 60.2 MPa \sqrt{m} (54.8 ksi \sqrt{in}) and an average K_{Isc} value of 15.9 MPa \sqrt{m} (14.5 ksi \sqrt{in}) in a 3.5% NaCl solution (Ref 6). Table 15 presents longitudinal and transverse tensile and plane-strain fracture toughness data for both air-melted and vacuum arc remelted 300M steel. R.R. Moore fatigue test results on transverse specimens indicate fatigue limits of about 580 MPa (84 ksi) for air-melted 300M and about 675 MPa (98 ksi) for VAR 300M; the latter represents an improvement of about 17% over air-melted 300M. In

the same study, there was no significant difference in transverse fatigue limit between VAR 300M and ESR 300M that had been hot reduced only 75% from the ingot. In all these studies, remelted steels (whether VAR or ESR) had better ductility and toughness, particularly in the transverse direction, although there did not appear to be any significant difference between longitudinal and transverse plane-strain fracture toughness values.

Table 15 Average mechanical properties of air-melted and vacuum arc remelted heats of 300M steel

Hot reduced 96 to 98% to round-cornered square billets, about 100 × 100 mm (4 × 4 in.). Specimens were normalized at 925 °C (1700 °F), oil quenched from 870 °C (1600 °F), refrigerated, and double tempered, 2 + 2 h at 315 °C (600 °F).

D-6a and D-6ac Steel

Ladish D-6a is a low-alloy ultrahigh-strength steel developed for aircraft and missile structural applications. It is designed primarily for use at room-temperature tensile strengths of 1800 to 2000 MPa (260 to 290 ksi). The steel D-6a maintains a very high ratio of yield strength to tensile strength up to a tensile strength of 1930 MPa (280 ksi), combined with good ductility. It has good notch toughness, which results in high resistance to impact loading. It is deeper hardening than 4340 and does not exhibit temper embrittlement. It retains high strength at elevated temperature. Susceptibility of D-6a to stress-corrosion cracking and corrosion fatigue in moist and aqueous environments is comparable to that of 300M steel at the same strength level. The alloy is called D-6a when produced by air melting in an electric furnace and D-6ac when produced by air melting followed by vacuum arc remelting. The mechanical properties of D-6a and D-6ac differ somewhat as a result of the differences in melting practices. Other characteristics of the two steels, including processing behavior, are identical.

D-6a and D-6ac are available as bar, rod, billet, and forgings and can be made as flat-rolled products (sheet and plate) as well. These forms are used in landing gear and critical structural components for aircraft, motor cases for solid-fuel rockets, shafts, gears, springs, dies, dummy blocks, and backer blocks.

Processing. To forge D-6a, it should be heated to a maximum temperature of 1230 °C (2250 °F); forging should be finished above 980 °C (1800 °F). Finished forgings should be cooled slowly, either in a furnace or embedded in a suitable insulating medium such as ashes or lime. For maximum machinability, the parts should be charged into a 650 °C (1200 °F) furnace immediately after forging and held for 12 h; temperature should be increased to 900 °C (1650 °F) and held for a time period that depends on section size; parts should be cooled to 650 °C (1200 °F), held 10 h, and finally air cooled to room temperature.

The material D-6a, even in heavy sections, can be welded provided that the techniques and controls normally employed for welding medium-carbon, high hardenability alloy steels are used. Welding rod of the same composition should be used. For critical applications, gas tungsten arc welding is preferred; filler metal wire should be of vacuum-melted stock containing less carbon than is in the base metal and minimum amounts of phosphorus, sulfur, and dissolved gases. Welds made in this manner will have higher toughness than that of the base metal, but slightly lower strength. Pre-heat and interpass temperatures of 230 to 290 °C (450 to 550 °F) are recommended. Highly restrained weldments should be postheated $1\frac{1}{2}$ h at 300 to 330 °C (575 to 625 °F) and cooled in still air. When the weldments reach 150 °C (300 °F), they should be charged immediately into a furnace for stress relieving at 650 to 700 °C (1200 to 1300 °F).

Annealed D-6a has a machinability rating of 50 to 55% (B1112, 100%). When the steel is to be severely cold formed, it is usually normalized and then spheroidized before working.

Heat Treatments. The standard heat treatments that apply to D-6a and D-6ac steels are:

- *Normalize:* Heat to 870 to 955 °C (1600 to 1750 °F) and hold for a time period that depends on section thickness; air cool
- *Anneal:* Heat to 815 to 845 °C (1500 to 1550 °F) and hold for a time period that depends on section thickness or furnace load; furnace cool to 540 °C (1000 °F) at a rate no greater than 28 °C/h (50 °F/h); and then air cool to room temperature
- *Harden:* Austenitize at 845 to 900 °C (1550 to 1650 °F) for $\frac{1}{2}$ to 2 h. Sections no thicker than 25 mm (1 in.) may be air cooled. Sections thicker than 25 mm (1 in.) may be oil quenched to 65 °C (150 °F) or salt quenched to 205 °C (400 °F) and then air cooled. For optimum dimensional stability, "aus-bay" quench in a furnace at 525 °C (975 °F), equalize the temperature, and then quench in an oil bath held at 60 °C (140 °F) or quench in 250 °C (400 °F) salt and air cool. The cooling rate during quenching significantly affects fracture toughness. For high fracture toughness, especially in heavy sections, austenitize at 925 °C (1700 °F), aus-bay quench to 525 °C (975 °F), equalize, and oil quench to 60 °C (140 °F)
- *Temper:* Immediately after hardening, hold 2 to 4 h in the range of 200 to 700 °C (400 to 1300 °F), depending on desired strength or hardness
- *Spheroidize:* Heat to 730 °C (1350 °F) and hold 5 h; increase temperature to 760 °C (1400 °F) and hold 1 h; furnace cool to 690 °C (1275 °F) and hold 10 h; furnace cool to 650 °C (1200 °F) and hold 8 h; air cool to room temperature
- *Stress relieve:* Heat to an appropriate temperature in the range of 540 to 675 °C (1000 to 1250 °F) and hold for 1 to 2 h; air cool

Properties. The effect of tempering temperature on typical room-temperature hardness of D-6a steel bar is shown in Fig. 5; other mechanical properties of D-6a bar are given in Table 16. Tensile properties of heat-treated D-6ac billet material are given in Table 17. D-6a maintains impact resistance to very low temperatures (Fig. 6). Typical elevated-temperature tensile properties of D-6a are presented in Table 18, and in Table 19 room-temperature tensile properties after 10 h and 100 h exposures at 540 °C (1000 °F) are compared with properties of unexposed material. Data on stress-rupture life at 480 and 540 °C (900 and 1000 °F) are presented in Fig. 7. The effects of tempering temperature on smooth-bar and notched-bar tensile strengths are plotted in Fig. 8. As mentioned in the section on heat treatment, the rate of cooling during quenching has a significant effect on fracture toughness. When the steel is heat treated for high fracture toughness (as outlined above), a K_{Ic} value of 99 to 104 MPa \sqrt{m} (90 to 95 ksi \sqrt{in}) can be obtained at a tensile strength of about 1650 MPa (240 ksi) (Ref 7). The alloy is susceptible to stress-corrosion cracking; the K_{Isc} value, in both water and 3.5% NaCl solution, appears to be less than 16 MPa \sqrt{m} (15 ksi \sqrt{in}). The steel has high fatigue strength; Table 20

presents data for both D-6a and D-6ac derived from rotating-beam fatigue tests, and Table 21 gives data for rapid-cycle (about 186 kHz) tension-tension and tension-compression fatigue tests at room and elevated temperatures.

6150 Steel

AISI/SAE 6150 is a tough, shock-resisting, shallow-hardening chromium-vanadium steel with high fatigue and impact resistance in the heat-treated condition. It can be nitrided for maximum surface hardness and abrasion resistance; nitriding characteristics are similar to those of 4140 and 4340 steels. The steel 6150 may be forged from temperatures up to 1200 °C (2200 °F), but the usual temperature range is 1175 to 950 °C (2150 to 1750 °F). Parts made of 6150 steel can readily be welded using any of the standard welding methods. After welding, parts should be normalized and then hardened and tempered to the desired hardness.

For best machinability, 6150 should be in the annealed condition. Machinability rating is about 55% (B1112, 100%). As with other low-alloy steels of about the same carbon content, the optimum microstructure for machining is coarse lamellar pearlite and/or coarse spheroidite. Chips are continuous and springy, which can make the steel difficult to machine.

Available as bar, rod, plate, sheet, strip, wire, and tubing, 6150 steel may be forged or cast into shapes. Typical applications include gears, pinions, springs (both coiled and flat), shafts, axles, heavy duty pins, bolts, and machinery parts.

Heat Treatments. The heat treatments that apply to 6150 steel are:

425	800	1570	228	1450	210	10	37	461
480	900	1360	197	1210	175	11	41	401

8640 Steel

AISI/SAE 8640 was especially designed to provide the maximum hardenability and best combination of properties possible with minimum alloying additions. The material 8640 is an oil-hardening steel, but may be water hardened if precautions are taken to prevent cracking. It exhibits properties similar to those of 4340, except that its strength in large sections is not as high.

This steel is available as billets, bars, rods, forgings and castings. It is used to make gears, pinions, shafts, axles, studs, fasteners, machinery parts, and forged hand tools.

Processing. The 8640 steel may be forged at temperatures up to 1200 °C (2200 °F), but is usually forged in the range from 1175 to 950 °C (2150 to 1750 °F). Forged parts are cooled slowly from the forging temperature, then annealed prior to machining.

This steel can be welded by any of the standard welding methods. Because 8640 has some air-hardening tendencies, preheating to 150 to 260 °C (300 to 500 °F) before welding and postheating after welding are recommended. Stress relieving at 600 to 650 °C (1100 to 1200 °F) is quite satisfactory for most welded parts.

Cold-drawn 8640 has a machinability rating of 64% (B1112, 100%). Annealing prior to cold drawing can improve machinability by about 10%.

Heat Treatments. The heat treatments that apply to 8640 steel are:

- *Normalize:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold for a time period that depends on section thickness; air cool
- *Anneal:* Heat to 845 to 870 °C (1550 to 1600 °F) and hold for a time period that depends on section thickness or furnace load; furnace cool
- *Harden:* Austenitize at 815 to 845 °C (1500 to 1550 °F); quench in oil or water
- *Temper:* Hold at least $\frac{1}{2}$ h at 200 to 650 °C (400 to 1200 °F)
- *Spheroidize:* Heat to 705 to 720 °C (1300 to 1325 °F) and hold several hours; furnace cool

Properties. Variations in properties of heat-treated round sections of 8640 with tempering temperature are given in Table 24. Variations in properties with section size (mass effect) are given in Table 25. Impact behavior is illustrated in Fig. 10.

Ultrahigh-Strength Steels

Revised by Thoni V. Philip, TVP Inc.; and Thomas J. McCaffrey, Carpenter Steel Division of Carpenter Technology Corporation

Medium-Alloy Air-Hardening Steels

The ultrahigh-strength steels H11 modified (H11 mod) and H13, which are popularly known as 5% Cr hot-work die steels, are discussed in this section. Besides being extensively used in dies, these steels are widely used for structural applications, but not as widely as they once were, primarily because of the development of several other steels at essentially the same cost but with substantially greater fracture toughness at equivalent strength. Nonetheless, H11 mod and H13 possess some attractive features. Both can be hardened through in large sections by air cooling. The chemical compositions of these steels are given in Table 1.

H11 Modified

This steel is a modification of the martensitic hot-work die steel AISI H11, the significant difference being a slightly higher carbon content. The H11 mod steel can be heat treated to strengths exceeding 2070 MPa (300 ksi). It is air hardened, which results in minimal residual stress after hardening. Because H11 mod is a secondary hardening steel, it develops optimum properties when tempered at temperatures above 510 °C (950 °F). The high tempering temperatures used for this steel provide substantial stress relief and stabilization of properties so that the material can be used to advantage at elevated temperatures. This also enables heat-treated parts to be warm worked at temperatures as much as 55 °C (100 °F) below the prior tempering temperature or to be preheated for welding. At high strength levels (those exceeding 1800 MPa, or 260 ksi), H11 mod has good ductility, impact strength, notch toughness, and fatigue life, as well as high creep and rupture strength, at temperatures up to about 650 °C (1200 °F). It is used for parts requiring maximum levels of strength, ductility, toughness, fatigue resistance, and thermal stability at temperatures between -75 and 540 °C (-100 and 1000 °F). At elevated temperatures, parts should be protected from corrosion (oxidation) by an appropriate surface treatment. The material H11 mod has good formability in the annealed condition and is readily welded. It is subject to hydrogen embrittlement. Its fracture toughness is rather low; if it is used in critical applications at yield strengths above 1380 MPa (200 ksi), care should be taken to eliminate small discontinuities.

The H11 mod steel is available as bar, billet, rod, wire, plate, sheet, strip, forgings, and extrusions. It is used for parts requiring high strength combined with either strength retention at elevated temperatures or moderate corrosion resistance. Typical applications include aircraft landing gear components, airframe components, internal parts for steam and gas turbines, fasteners, springs, and hot-work dies.

Parts to be used at elevated temperatures are commonly protected by nickel-cadmium plating. If such plating is done, baking to avoid hydrogen-induced delayed cracking is recommended. Alternatively, part surfaces may be protected from oxidation by hot dipping in aluminum or by applying a heat-resistant paint.

Processing. The material H11 mod is readily forged from 1120 to 1150 °C (2050 to 2100 °F). Preferably, stock should be preheated at 790 to 815 °C (1450 to 1500 °F) and then heated uniformly to the forging temperature. Forging should not be continued below 925 °C (1700 °F). Stock may be reheated as often as necessary. Because H11 mod is air hardening, it must be cooled slowly after forging to prevent stress cracks. After forging, the part should be charged into a furnace at about 790 °C (1450 °F); soaked until the temperature is uniform; and then slowly cooled, either while retained in the furnace or buried in an insulating medium such as lime, mica, or a siliceous filler material such as silocel. When the forging has cooled, it should be annealed.

The steel H11 mod, even in heavy sections, is readily welded. Fusion welding generally is accomplished with an inert-gas process or with coated electrodes. Filler metal should be of the same general composition. Preheating at about 540 °C (1000 °F) is recommended, and during welding the temperature should be maintained above 315 °C (600 °F). Thin sheet can be welded without preheating, but should be post-heated at about 760 °C (1400 °F). Weldments, especially heavy-section weldments, should be cooled slowly in a furnace or an insulating medium. All weldments should be fully annealed after welding. Weldments of H11 mod have shown weld metal strength and ductility equal to or greater than those of the base metal. The machinability rating for H11 mod is about 60% of the rating for 1% C steel, or about 45% of that for B1112.

Heat Treatments. The standard heat treatments that apply to H11 mod steel are:

- *Normalize:* Generally not necessary. For effective homogenization, heat to about 1065 °C (1950 °F), soak 1 h for each 25 mm (1 in.) of thickness; air cool. Anneal immediately after the part reaches room temperature. Note: There is a possibility that H11 mod may crack during this treatment
- *Anneal:* Heat to 845 to 885 °C (1550 to 1625 °F) and hold to equalize temperature; cool very slowly in the furnace to about 480 °C (900 °F) and then more rapidly to room temperature. This treatment should produce a fully spheroidized microstructure free of grain boundary carbide networks
- *Harden:* Preheat to 760 to 815 °C (1400 to 1500 °F) and then raise the temperature to 995 to 1025 °C (1825 to 1875 °F) and hold 20 min plus 5 min for each 25 mm (1 in.) of thickness; air cool. For a few applications, oil quenching from the low end of the hardening temperature range may be done. Air cooling, which produces less distortion than oil quenching, is more commonly employed
- *Temper:* Heat at the secondary hardening temperature of about 510 °C (950 °F) for maximum hardness and strength, or above the secondary hardening peak to temper back to a lower hardness or strength. A minimum of 1 h at temperature should be allowed, but preferably parts should be double tempered: Hold 2 h at temperature, cool to room temperature, and then hold 2 h more at temperature. Triple tempering is more desirable, especially for critical parts. For high-temperature applications, parts should be tempered at a temperature above the maximum service temperature to guard against unwanted changes in properties during service
- *Stress relieve:* Heat to 650 to 675 °C (1200 to 1250 °F); cool slowly to room temperature. This treatment is often used to achieve greater dimensional accuracy in heat-treated parts by stress relieving rough-machined parts, then finish machining, and finally heat treating to the desired hardness
- *Nitride:* Finish-machined and heat-treated parts should be gas or liquid nitrided at temperatures of about 525 °C (980 °F). The depth of the nitrided case depends on time at temperature. For example, gas nitriding in 20 to 30% dissociated ammonia for 8 to 48 h normally produces a case depth of about 0.2 to 0.35 mm (0.008 to 0.014 in.)
- *Bake:* After plating in an acid bath, or after other processing that might introduce hydrogen into metal, parts should be baked 24 h or longer at 190 °C (375 °F) or above

Properties. Variations in hardness of H11 mod with tempering temperature are plotted in Fig. 11. Variations in typical room-temperature longitudinal mechanical properties with tempering temperature are given in Table 26. This steel is quite notch tough; the ratio of notched-bar tensile strength ($K_t = 3.3$) to smooth-bar tensile strength at room temperature is about 1.4 at a smooth-bar tensile strength of 1380 MPa (200 ksi) and about 1.15 at 1930 MPa (280 ksi).

Fig. 11 Variation in hardness with tempering temperature for H11 mod steel. All specimens air cooled from 1010 °C (1850 °F) and double tempered, 2 + 2 h at temperature. AQ, as quenched

Because of secondary hardening characteristics, H11 mod has good temper resistance, which results in high hardness and strength at elevated temperatures. Hot hardness of H11 mod tempered to three room-temperature hardness levels is plotted in Fig. 12. Regardless of the initial room-temperature hardness, the hot hardness drops precipitously to levels corresponding to the annealed state at temperatures above 620 °C (1150 °F). Short-time elevated-temperature tensile properties of bar stock tempered at 540, and 565, and 595 °C (1000, 1050, and 1100 °F) are given in Table 27. The

high temper resistance of H11 mod is indicated in Table 28, which gives room-temperature tensile properties after prolonged exposure to elevated temperatures. This material has fairly good stress-rupture properties at temperatures below 650 °C (1200 °F), as shown in Table 29.

Fig. 12 Typical hot hardness of H11 mod steel. Specimens air cooled from 1010 °C (1850 °F) and double tempered, 2 + 2 h at indicated tempering temperature. Rockwell hardness converted from microhardness values

The steel H11 mod has comparatively low fracture toughness, but has good resistance to stress-corrosion cracking compared to other ultrahigh-strength steels heat treated to the same strength. In a four-point bend test, plate 13 mm ($\frac{1}{2}$ in.) thick heat treated to 1295 MPa (188 ksi) yield strength by tempering at 595 °C (1100 °F) had a room-temperature K_{Ic} value of 59 MPa \sqrt{m} (54 ksi \sqrt{in}). The K_{Isc} value in 3.5% NaCl solution was 33 MPa \sqrt{m} (30 ksi \sqrt{in}). In another bend test (Ref 8), 12.7 mm plate with a yield strength of about 1450 MPa (210 ksi) resulting from tempering at 580 °C (1080 °F) had K_{Ic} values of 37 MPa \sqrt{m} (34 ksi \sqrt{in}) at room temperature and 60 MPa \sqrt{m} (55 ksi \sqrt{in}) at 93 °C (200 °F).

Significant improvements in H11 mod properties such as transverse ductility and toughness, particularly in large sections, can be achieved by vacuum arc remelting and electroslag remelting, both of which result in greater homogeneity and cleanliness of the steel. A comparison of midradius transverse tensile properties of air-melted and vacuum arc remelted billets is presented in Table 30. Each value is the average of four tests, two from the top of the ingot, and two from the bottom.

H13 Steel

AISI H13 is a 5% Cr ultrahigh-strength steel similar to H11 mod in composition, heat treatment, and many properties. The main difference in composition is the higher vanadium content of H13 (see Table 1); this leads to a greater dispersion of hard vanadium carbides, which results in higher wear resistance. Also, H13 has a slightly wider range of carbon content than does H11 mod. Depending on the producer, the carbon content of H13 may be near the high or low side of the accepted range, with a corresponding variation in strength and ductility for a given heat treatment.

Like H11 mod, H13 is a secondary hardening steel. It has good temper resistance and maintains high hardness and strength at elevated temperatures. It is deep hardening, which allows large sections to be hardened by air cooling. H13 steel can be heat treated to strengths exceeding 2070 MPa (300 ksi); like H11 mod, it has good ductility and impact strength. With standard heat treatment, the fracture toughness of H13 appears to be even lower than that of H11 mod.

The material H13 has good resistance to thermal fatigue. Hot-work tooling made of H13 can be safely water cooled between hot-working operations. Its resistance to thermal fatigue, erosion, and wear has made it a preferred die material for aluminum and magnesium die casting, as well as for many other hot-work applications. However, H13 is subject to hydrogen embrittlement. It can be nitrided for additional wear resistance.

Although H13 has not been used as widely as H11 mod as an ultrahigh-strength constructional steel, the similarities in properties make H13 equally attractive for such applications. This is particularly true in noncritical service in which slightly higher wear resistance is an advantage.

The H13 steel is available as bar, rod, billet, and forgings. Typical hot-work applications include die casting dies, inserts, cores, ejector pins, plungers, sleeves, slides, forging dies, extrusion dies, dummy blocks, and mandrels. Other tooling and structural applications include punches, shafts, beams, torsion bars, shrouds, and ratchets.

Processing. For forging, H13 steel is heated slowly and uniformly to a temperature of 1090 to 1150 °C (2000 to 2100 °F), preferably after preheating at 760 to 815 °C (1400 to 1500 °F). The steel should be thoroughly heated before forging. Forging should not be done below 900 °C (1650 °F), but the parts may be reheated as often as necessary. Because H13 is air hardening, parts should be cooled slowly after forging. Simple forgings may be cooled in an insulating medium such as dry ashes, lime, or expanded mica. The best practice for large forgings is to place in a heated furnace at about 790 °C (1450 °F), soak until the temperature is uniform, shut off the furnace, and let cool slowly. Parts should then be given a full spheroidizing anneal.

When annealed H13 is welded, it should be preheated to 540 °C (1000 °F), or to as high a temperature as is practical, preferably in a furnace to ensure uniform, stress-free preheating. Uncoated rod, preferably of the same general composition, should be used, with shielded-arc equipment. The temperature of the part should be kept above 315 °C (600 °F), and the part reheated if necessary, until welding has been completed. After welding, the part should be cooled slowly in an insulating medium and given a full anneal. A heat-treated part such as a die can be welded using the same procedure, preferably preheating the part in a furnace to a temperature about 55 °C (100 °F) below the original tempering

temperature. After welding, the part should be placed in a furnace at the preheating temperature and cooled slowly to room temperature. It is recommended that the part then be reheated to just below the original tempering temperature and air cooled. This helps to relieve welding stresses and blend the hardness of the weld area into that of the base metal. Regardless of the situation, adequate preheating and slow cooling are essential to minimize the risk of cracking during welding.

Fully annealed H13 has a machinability rating that is about 70% of the rating for 1% C tool steel, or about 45% of that for B1112.

Heat Treatments. The heat treatments that apply to H13 steel are:

- *Normalize:* Not recommended for H13. Some improvement in homogeneity can be obtained by preheating to about 790 °C (1450 °F), heating slowly and uniformly to 1040 to 1065 °C (1900 to 1950 °F), holding 1 h for each 25 mm (1 in.) of thickness, and then air cooling. Just before the part reaches room temperature, it should be recharged into a furnace and given a full anneal. Note: There is a risk of cracking during this treatment, especially if done in a furnace in which the atmosphere is not controlled to prevent surface decarburization
- *Anneal:* Heat uniformly to 860 to 900 °C (1575 to 1650 °F) in a furnace with controlled atmosphere, or with the part packed in a neutral compound, so that decarburization is prevented. Cool very slowly in the furnace to about 480 °C (900 °F); then cool more rapidly to room temperature. This treatment results in a fully spheroidized microstructure
- *Harden:* Heat slowly and uniformly to 995 to 1025 °C (1825 to 1875 °F) and soak 20 min plus 5 min for each 25 mm (1 in.) of thickness; preheating at 790 to 815 °C (1450 to 1500 °F) is usually recommended for thick parts. Air cool in still air. Air cooling is usually done from the high side of the hardening temperature range. For a few applications, H13 may be oil quenched from the low side of the hardening temperature, but at the risk of distortion or cracking
- *Temper:* Heat at the secondary hardening peak of about 510 °C (950 °F) for maximum hardness and strength, or at higher temperatures to temper back to a lower level of hardness or strength. Double tempering, that is, 2 h at temperature, air cooling, then 2 h more at temperature, is recommended. Occasionally, triple tempering may be desirable
- *Stress relieve:* Heat to 650 to 675 °C (1200 to 1250 °F) and soak 1 h or more; cool slowly to room temperature. This treatment is often used to achieve greater dimensional accuracy in heat-treated parts by stress relieving rough-machined parts, then finish machining, and finally heat treating to the desired hardness
- *Nitride:* Finish-machined and heat-treated parts may be nitrided to produce a highly wear-resistant surface. Because it is carried out at the normal tempering temperature, nitriding can serve as the second temper in a double-tempering treatment. The depth of the nitrided case depends on the time at temperature. For example, gas nitriding at 510 °C (950 °F) for 10 to 12 h produces a case depth of 0.10 to 0.13 mm (0.004 to 0.005 in.) and for 40 to 50 h produces a case depth of about 0.3 to 0.4 mm (0.012 to 0.016 in.). Parts that have been deep nitrided are usually lapped or gently surface ground to remove the thin, brittle white layer. Selective nitriding is sometimes done to produce a nitrided case only where it is needed. Copper plating is preferred for stopping off areas that are not to be nitrided; stop-offs containing lead should be avoided, because lead embrittles H13 steel

Properties. The properties presented in this section are for H13 with a carbon content in the middle of the composition range (for composition, see Table 1). Somewhat different properties should be expected when the carbon content is near either the high end or the low end of the range.

The variation in hardness of H13 with tempering temperature is plotted in Fig. 13. Room-temperature longitudinal mechanical properties of bars tempered to different hardness levels are given in Table 31. Because it is a secondary hardening steel, H13 maintains high hardness and strength at elevated temperatures. Values of hot hardness for specimens tempered to three different hardness levels are presented in Fig. 14. Typical short-time tensile properties of H13 bar tempered to different hardness levels are listed in Table 32 for various service (test) temperatures. Regardless of initial room-temperature hardness, H13 attains essentially the same low properties at 650 °C (1200 °F). Like H11 mod, H13 has

good impact properties at temperatures up to 540 °C (1000 °F). Charpy V-notch impact energies at subzero, room, and elevated temperatures are compared in Table 33.

Little work has been done to determine the fracture toughness of H13. It appears that with the standard heat treatment H13 has slightly lower fracture toughness than H11 mod. Available data on fracture toughness of H13 are given in Table 34.

(a) Values should not be used for design purposes because they represent material that was not heat treated in the usual manner, but was cooled from an austenitizing temperature higher than normal.

Vacuum arc remelted (VAR) and electroslag remelted (ESR) H13 have better cleanliness and homogeneity than air melting H13. The VAR and ESR processes are used to produce steels with superior ductility, impact strength, and fatigue resistance, especially in the transverse direction, and particularly in large section sizes. Table 35 compares room-temperature transverse mechanical properties of air-melted and ESR H13 in large section sizes.

In axial (tension-tension) fatigue tests, the life of ESR H13 was superior to that of air-melted H13 (Fig. 15). When both were fatigue tested under fully reversed stresses, there was no significant difference in the life of longitudinal specimens. However, for transverse specimens, the life of ESR H13 was significantly better (Fig. 16).

Fig. 15 Tension-tension fatigue curves for longitudinal specimens of air-melted and electrosag-remelted heats of H13 steel. Axial fatigue tests performed in an Ivy machine at a frequency of 60 Hz; the alternating stress was 67% of the mean stress for all tests ($R = 0.2$). Arrows signify tests terminated without any sign of fatigue cracking.

Ultrahigh-Strength Steels

Revised by Thoni V. Philip, TVP Inc.; and Thomas J. McCaffrey, Carpenter Steel Division of Carpenter Technology Corporation

High Fracture Toughness Steels

High-strength, high fracture toughness steels as described in this article are commercial structural steels capable of a yield strength of 1380 MPa (200 ksi) and a K_{Ic} of $100 \text{ MPa}\sqrt{m}$ ($91 \text{ ksi}\sqrt{in}$). (These steels also exhibit stress corrosion cracking resistance.) A number of developmental steels that are not fully commercial alloys are excluded from this discussion. The HP-9-4-30 and AF1410 steels, however, are discussed below.

Both these alloys are of the Ni-Co-Fe type and have a number of similar characteristics. Both are weldable, and the melt practice requires a minimum of VAR. Control of residual elements to low levels is required for optimum toughness. The machining practices used for 4340 steel are generally satisfactory; however, Ni-Co-Fe alloys are considered more difficult to machine than are alloy steels.

HP-9-4-30 Steel

During the 1960s, Republic Steel Corporation introduced a family of four weldable steels, all of which had high fracture toughness when heat treated to medium/high strength levels. Only HP-9-4-30 has been produced in significant quantities and is comparable to the high-strength, high fracture toughness steels of this article. The chemical composition is given in Table 1. The HP-9-4-30 steel is usually electric arc melted and then vacuum arc remelted. Forging temperatures should not exceed 1120 °C (2050 °F). The HP-9-4-30 steel is capable of developing a tensile strength of 1520 to 1650 MPa (220 to 240 ksi) with a plain-strain fracture toughness of 100 MPa \sqrt{m} (91 ksi \sqrt{in}). This steel has deep hardenability and can be fully hardened to martensite in sections up to 150 mm (6 in.) thick. The HP-9-4-30 steel in the heat-treated condition can be formed by bending, rolling, or shear spinning. Heat-treated parts can readily be welded. Tungsten arc welding under inert-gas shielding is the preferred welding process. Neither postheating nor postweld heat treating is required. After welding, parts may be stress relieved at about 540 °C (1000 °F) for 24 h. This is a stress-relieving treatment and has no adverse effect on the strength or toughness of either the weld metal or the base metal. The HP-9-4-30 steel is available as billet, bar, rod, plate, sheet, and strip. It has been used for aircraft structural components, pressure vessels, rotor shafts for metal forming equipment, drop hammer rods, and high-strength shock-absorbing automotive parts.

Heat Treatments. The heat treatments that apply to HP 9-4-30 steel are:

- *Normalize:* Heat to 870 to 925 °C (1600 to 1700 °F) and hold 1 h for each 25 mm (1 in.) of thickness (1 h minimum); air cool
- *Anneal:* Heat to 620 °C (1150 °F) and hold 24 h; air cool
- *Harden:* Austenitize at 830 to 860 °C (1525 to 1575 °F) and hold 1 h for each 25 mm (1 in.) of thickness (1 h minimum); water or oil quench. Complete the martensitic transformation by refrigerating at least 1 h at -87 to -60 °C (-125 to -75 °F); allow to warm to room temperature
- *Temper:* Hold at 200 to 600 °C (400 to 1100 °F), depending on desired final strength; double tempering is preferred. The most widely used tempering treatment is double tempering, that is, 2 h at temperature, air cooling, and then 2 h more at temperature, at a temperature ranging from 540 to 580 °C (1000 to 1075 °F)
- *Stress relieve:* Usually required only after welding restrained sections. Heat to 540 °C (1000 °F) and hold 24 h; air cool to room temperature

Properties. Table 36 presents room-temperature mechanical properties of HP 9-4-30 double tempered at three different temperatures. The data for material double tempered at 540 °C (1000 °F) represent minimum mechanical properties for this condition: properties listed for the other conditions may be considered typical. Smooth-bar fatigue strengths at 10⁷ cycles of 830 MPa (120 ksi) have been reported for material double tempered at 540 °C (1000 °F); the corresponding notched-bar fatigue strength was 380 MPa (55 ksi).

- (a) Oil quenched from 845 °C (1550 °F), refrigerated to -73 °C (-100 °F) and double tempered at 205 °C (400 °F).
- (b) Same heat treatment as (a) except double tempered at 550 °C (1025 °F).
- (c) For sections forged to 75 mm (3 in.) or less in thickness (or to less than 0.016 m², or 25 in.², in total cross-sectional area), quenched to martensite and double tempered at 540 °C (1000 °F)

The HP 9-4-30 steels have good thermal stability, which makes them suitable for long-term service at temperatures up to at least 370 °C (700 °F). Table 37 gives short-time tensile properties and fracture toughness values for 25 mm (1 in.) plate tested at room temperature and at 260 and 345 °C (500 and 650 °F). In the same study, it was reported that the fatigue crack propagation rate was not affected by temperatures up to 345 °C (650 °F). Room-temperature mechanical properties of material exposed to elevated temperature for 1000 h are given in Table 38. Stresses to cause rupture in 100 h have been reported as 860 MPa (125 ksi) at 480 °C (900 °F) and 380 MPa (55 ksi) at 540 °C (1000 °F) for material double tempered at 540 °C (1000 °F). Corresponding values for 100 h life are 585 MPa (85 ksi) at 480 °C (900 °F) and 195 MPa (28 ksi) at 540 °C (1000 °F).

Table 37 Mechanical properties of HP 9-4-30 steel at three test temperatures

AF1410 Steel

The steel AF1410 was an outgrowth of the U.S. Air Force sponsorship of the advanced submarine hull steels, the result of which was the development of the low-carbon Fe-Ni-Co type alloys. These alloys had significant stress corrosion cracking resistance. By raising the cobalt and carbon content, the ultimate tensile strength was increased to a typical 1615 MPa (235 ksi). This increase in strength was obtained while maintaining a K_{Ic} value of $154 \text{ MPa}\sqrt{m}$ ($140 \text{ ksi}\sqrt{in}$). This combination of strength and toughness exceeds that of other commercially available steels, and the alloy has been considered as a replacement for titanium in certain aircraft parts. The AF1410 material (see Table 1 for composition) is air hardenable in sections up to 75 mm (3 in.) thick. The preferred melting practice is presently vacuum induction melting followed by vacuum arc remelting (VIM/VAR). However, initially VIM and VIM/ESR practices were used. Melting practice requires that impurity elements be kept at very low levels to ensure high fracture toughness. Although forgeable to 1120 °C (2050 °F), at least a 40% reduction must be obtained below 900 °C (1650 °F) to attain maximum properties. Weldability is good using a continuous wave (CW)-gas tungsten arc welding (GTAW) process, provided that high-purity wire is used and oxygen contamination is avoided. Information on stress-corrosion cracking is incomplete; however, it has been determined that at 52 HRC AF1410 has a K_{Isc} of $66 \text{ MPa}\sqrt{m}$ ($60 \text{ ksi}\sqrt{in}$). Obtainable as bar, billet, rod, plate, sheet, and strip, AF1410 has been used for aircraft structural components.

The microstructure of AF1410 consists of Fe-Ni lath martensite, precipitation on which produces the strengthening mechanism. Quenching from the austenitizing temperature produces a highly dislocated lath martensite that has a high toughness, as measured by the Charpy V-notch impact test (Fig. 17). Aging produces a complex series of changes in carbide structure. At approximately 425 °C (800 °F), Fe_3C is precipitated. At 455 °C (850 °F), Fe-Cr-Mo M_2C carbide is obtained, which at 480 °C (900 °F) will begin to produce a pure Mo-Cr M_2C carbide. By raising the temperature to 510 °C (950 °F), the M_2C will begin to coarsen; at 540 °C (1000 °F) M_2C will begin to be replaced by M_6C , which has little strengthening effect. The steel is normally austenitized and aged. The secondary hardening, which is due to the aging, produces a maximum tensile strength when aged at 480 °C (900 °F) using a 5 h aging time and a minimum impact energy when aged at 425 °C (800 °F), as shown in Fig. 17. When aged in the temperature range between 425 °C (800 °F) and 540 °C (1000 °F), the impact energy exhibits a maximum at about 508 °C (947 °F), as shown in Fig. 18. At aging temperatures above 540 °C (1000 °F), both the tensile strength and the impact energy decrease rather rapidly.

Fig. 17 Effect of aging temperature on impact energy (bottom) and yield strength (top) of AF1410 steel (VIM/VAR plate 15 mm, or $\frac{5}{8}$ in., thick). Heat treatments: Heat at 900 °C (1650 °F) for $\frac{1}{2}$ h and water quench; heat at 815 °C (1500 °F) for $\frac{1}{2}$ h and water quench; age for 5 h at indicated temperatures and air cool. AQ, as quenched. Source: Ref 1

Fig. 18 Effect of aging temperature on impact energy of AF1410 steel (VIM/VAR plate 15 mm, or $\frac{5}{8}$ in., thick). Heat treatments: See Fig. 17.

The steel is subject to austenite reversion during aging. At normal aging temperatures, the retained austenite is generally less than 1% by volume. However, 540 °C (1000 °F) or higher will produce large amounts of austenite, and these will weaken the matrix of the steel. The best combination of strength and ductility results from a 510 °C (950 °F) age.

Heat Treatment. The heat treatments that apply to AF1410 steel are:

- *Normalized and Overaged:* This is the condition the material is normally supplied for best machinability. Heat between 880 °C (1620 °F) and 900 °C (1650 °F), hold 1 h for each 25 mm (1 in.) of thickness; air cool and over age at 675 °C (1250 °F) for 5 h minimum
- *Anneal:* Usually, normalizing and overaging (above) are used to soften and stress relieve the product. A stress relief of 675 °C (1250 °F) may be applied to relieve mechanical stress
- *Harden:* Double austenitize, first at 870 to 900 °C (1600 to 1650 °F), hold 1 h for each 25 mm (1 in.) of thickness; oil, water, or air cool depending on section size; reaustenitize at 800 to 815 °C (1475 to 1500 °F); oil, water, or air cool. An alternative is to single austenitize at 800 to 815 °C (1475 to 1500 °F), hold 1 h for each 25 mm (1 in.) of thickness; oil, water, or air cool depending on section size
- *Quench:* Air cooling from the austenitizing temperature will produce tensile strength, toughness, and fatigue strength essentially equal to oil or water quenching in section sizes up to 75 mm (3 in.). Refrigeration treatment of -73 °C (-100 °F) is optional. The aim is to reduce the amount of retained austenite. There is no real evidence that such a treatment has any substantial effect on the material or the mechanical properties
- *Aging:* Age at 480 to 510 °C (900 to 950 °F) 5 to 8 h. Air cooling is normally employed

Properties. Tensile strength properties and impact energy for VIM/VAR melted plate quenched in air, water, or vermiculite and cooled following austenitizing are shown in Table 39. The heat treatments showed some effect on the tensile and impact properties for both 15 mm ($\frac{5}{8}$ in.) and 75 mm (3 in.) VIM/VAR melted plate.

Table 39 Effect of various heat treatments on mechanical properties of a cobalt-nickel steel (VIM/VAR plate of AF1410 steel)

Heat treatment ^{(a)(b)}	Ultimate strength		Yield strength		Elongation, %	Reduction in area, %	Charpy V-notch

Source: Ref 1

- (a) Time at 900 °C (1650 °F) or 815 °C (1500 °F) is as follows: 1 h for the 15 mm ($\frac{5}{8}$ in.) plate or 3 h for the 75 mm (3 in.) plate.
- (b) Initial and final treatments: X = 900 °C (1650 °F) for 1 h with air cooling and 675 °C (1250 °F) for 8 h with air cooling; Y = 900 °C (1650 °F) for 3 h with air cooling and 675 °C (1250 °F) for 8 h with air cooling; Z = 510 °C (950 °F) for 5 h with air cooling.
- (c) 815 °C (1500 °F) for the time per (a) and water quenching.
- (d) 815 °C (1500 °F) for the time per (a) with air cooling and a refrigeration treatment of -73 °C (-100 °F).
- (e) 815 °C (1500 °F) for the time per (a) with vermiculite cool and a refrigeration treatment of -73 °C (-100 °F).
- (f) 900 °C (1650 °F) for time per (a) with air cooling, 815 °C (1500 °F) for time per (a) with air cooling, and refrigeration at -73 °C (-100 °F).
- (g) 900 °C (1650 °F) for time per (a) with water quench, 815 °C (1500 °F) for time per (a) with water quench, 815 °C (1500 °F) for time per (a) with water quench, and 510 °C (950 °F) for 5 h with air cooling.

Room-temperature tensile properties after exposure to long-term elevated temperatures show some degradation after 500 h (Fig. 19). Fracture toughness, tensile properties, and impact energy of VIM/VAR melted 50 mm (2 in.) plate quenched and aged at 510 °C (950 °F) (a premachining heat treatment had been applied) are shown after quenching in different media (Table 40). Axial load fatigue data are provided in Fig. 20. Maximum stress for 10^7 cycles is approximately 690 MPa (100 ksi) for $K_t = 1$. Comparison of fatigue crack growth rate in low-humidity air (Fig. 21) and in $3\frac{1}{2}\%$ saltwater solution (Fig. 22) indicates the relative insensitivity of AF1410 to saltwater exposure.

Fig. 19 Effect of exposure to elevated temperature on room-temperature tensile properties of AF1410 steel (VIM/VAR plate 30 mm, or $1\frac{1}{4}$ in., thick). Heat treatment: Heat at 900 °C (1650 °F) for $\frac{1}{2}$ h and water quench, heat at 815 °C (1500 °F) for $\frac{1}{2}$ h and water quench, and then heat at 510 °C (950 °F) for 5 h and air cool. Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Introduction

CARBON STEELS are produced in greater tonnage and have wider usage than any other metal because of their versatility and low cost. For about ten years before World War II, there was a trend toward replacing carbon steels with alloy steels. The scarcity of alloying elements at that time caused a reappraisal of carbon steels, and in many instances, users reverted to carbon grades. With rapidly rising costs and the prospect of permanent shortages of various alloying elements, this trend is continuing.

Carbon steels proved to be satisfactory upon reappraisal because:

- Hardenability, although less than that of alloy steels, was adequate for many parts, and for some parts, shallow hardening was actually advantageous because it minimized quench cracking
- Refinements in heat-treating methods, such as induction hardening and flame hardening, made it possible to obtain higher properties from carbon steels than was previously possible
- Many new compositions were added to the carbon steel group, permitting a more discriminating selection

More than 50 grades are nominally available in the 10xx-series carbon steels, and more than 30 grades are available in the resulfurized 11xx and 12xx series. Also available are about 20 grades in the 15xx series (originally 10xx series steels with higher than normal manganese contents, usually in the range of 1.00 to 1.65%). The versatility of carbon steels has been further extended by the addition of lead for improved machinability and of boron for greater hardenability and for improvement in cold heading.

In addition to the standard carbon and alloy steels, there is a specific class of high-strength low-alloy (HSLA) steels. These materials are normally furnished to mechanical property requirements rather than to composition ranges. These steels are generally not intended for quenching and tempering by the user. Their properties and characteristics are covered in the articles "High-Strength Structural and High-Strength Low-Alloy Steels" and "High-Strength Low-Alloy Steel Forgings" in this Volume.

Generally, alloy steels are not used without appropriate heat treatment. By far the largest tonnage of alloy steels is of the type with nominal carbon contents between about 0.25 and 0.55%. If an alloy steel is to be used for carburized parts, the nominal carbon content usually does not exceed 0.20%. Various combinations and amounts of manganese, silicon, nickel, chromium, molybdenum, vanadium, and boron are commonly present in these steels to enhance the properties of the quenched and tempered alloy.

The microstructure (tempered martensite or bainite) produced by quenching and tempering alloy steels is characterized by good toughness, that is, the capacity to deform without rupture, at a given strength level. The basic phenomenon of obtaining a favorable microstructure by heat treatment is also possible in plain carbon steels, although primarily in thin sections. Thus, the most important effect of alloying elements in steel is to induce the formation of martensite or bainite, and accompanying superior properties, in large sections. The level of hardness or strength of these structures is a function of the carbon content of the transformation products rather than of the alloying elements present.

The general effect of alloying elements dissolved in austenite is to decrease the rate of austenite transformation at subcritical temperatures. Because the desirable products of transformation in these steels (martensite and lower bainite) are formed at low temperatures, this decreased transformation rate is essential. Consequently, pieces can be cooled more slowly, or larger pieces can be quenched in a given medium, without transformation of austenite to the undesirable high-temperature products (pearlite or upper bainite). This function, decreasing the rate of transformation and thereby facilitating ultimate transformation to martensite or lower bainite, is known as hardenability, the most important effect of alloying elements in hardenable steels. By increasing hardenability, alloying elements greatly extend the potential for enhanced properties to the large sections required for many applications.

Many of the curves in this article and in the article "Hardenability Curves" in this Volume serve to illustrate the principle that, regardless of composition, tempered steels of the same hardness have approximately the same tensile strength.

The maximum (as-quenched) hardness of heat-treated steel depends primarily on the carbon content. Alloying elements have little effect on the maximum hardness that can be developed in steel, but they profoundly affect the depth to which this maximum hardness can be developed in a part of specific size and shape. Thus, for a specific application, one of the first decisions to be made is what carbon level is required to obtain the desired hardness. The next step is to determine

what alloy content will give the proper hardening response in the section size involved. This is not to imply that tempered martensitic steels are alike in every respect, regardless of composition, because the alloy content is responsible for differences in the preservation of strength at elevated temperatures; in abrasion resistance; in resistance to corrosion; and even, to a certain extent, in toughness. However, the similarities are sufficiently marked to permit reasonably accurate predictions of mechanical properties from hardness rather than from composition, thereby justifying the emphasis on hardenability as the most important function of the alloying elements.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Hardenability

Required hardenability is the most important factor influencing a choice between carbon- and alloy steel. It is now possible to purchase carbon steels produced to a specific hardenability band. As of 1989, there were six carbon H steels (1038H, 1045H, 1522H, 1524H, 1526H, and 1541H), nine carbon-boron H steels (15B21H, 15B28H, 15B30H, 15B35H, 15B37H, 15B41H, 15B46H, 15B48H, and 15B62H) and 70 standard alloy H steels for which hardenability data had been compiled. This establishes a more definite distinction between carbon and alloy steels than can be done by actual hardenability values because the latter are available as H steels in most of the tonnage grades. Tables 1 and 2 list the compositions of all the H steels.

Table 1 Composition of carbon and carbon-boron H steels

Source: Ref 1

- (a) Small quantities of certain elements may be found in alloy steel that are not specified or required. These elements are to be considered incidental and acceptable to the following maximum amounts: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to

0.06%.

- (b) For open hearth and basic oxygen steels, maximum sulfur content is to be 0.040%, and maximum phosphorus content is to be 0.035%. Maximum phosphorus and sulfur in basic electric furnace steels are to be 0.025% each.
- (c) Sulfur content range is 0.035/0.050%.
- (d) Electric furnace steel.
- (e) These steels contain 0.0005 to 0.003% B.

Carbon steels with low manganese (some grades as low as 0.30%) and a virtual absence of residual nickel, chromium, and molybdenum are the lowest in hardenability of all standard steels. This holds true for nearly all carbon levels, because in the absence of higher manganese or other alloying elements, carbon functions almost entirely to control maximum hardness and has only a minor effect on hardenability.

Most of the hardenable 1xxx-series carbon steels have 0.60 to 0.90% manganese, although several grades have higher and others have lower manganese contents. Those steels with a maximum manganese content between 1.00% and 1.65% have been renumbered and now constitute the 15xx series. The effect of manganese on the variation of strength with carbon content in as-hot-rolled carbon steels is shown in Fig. 1. Manganese has a marked effect on hardenability. Even a difference of 0.25% makes a significant difference on the end-quench hardenability of 0.50% carbon steel (Fig. 2).

Fig. 1 Effect of manganese and carbon on tensile strength of as-hot-rolled carbon steels

Fig. 2 Effect of carbon and manganese on end-quench hardenability of 1050 steel. The steels with 1.29 and 1.27% manganese contained 0.06% residual chromium. Steels with 1.07 and 1.04% manganese contained 0.06 and 0.08% residual chromium, respectively. No other residual elements were reported.

Considering the range of manganese that is available in carbon steels, it follows that a wide range of hardenability can exist. For example, 1541 steel frequently shows end-quench hardenability values higher than the minimum of the hardenability band for 1340 steel (Fig. 3). Thus, there is a gradual transition in hardenability from carbon grades to alloy grades.

Fig. 3 Comparison of 1340H and 1541H hardenability ranges. Source: Ref 1

Steels are not necessarily better because they are higher in hardenability. They are better only when higher hardenability is required. There are many applications for which minimum, rather than maximum, hardenability is needed, which accounts for the many low-manganese grades melted. For example, it is often desirable to produce thin layers of maximum hardness on shaft bearings or cam contours. This is usually accomplished by induction or flame hardening; however, if the hardened zone is too deep, an unfavorable pattern of residual stresses will be established, with resultant cracking in quenching or premature failure in service. In one instance, cams were made from standard 1050 steel (0.60 to 0.90% Mn) and induction hardened to 60 HRC to a depth of about 1.6 mm ($\frac{1}{16}$ in.). If the hardened zone became as deep

as 3.2 mm ($\frac{1}{8}$ in.), a significant number of parts cracked. Cracking was eliminated by using a modified grade of 1050 steel (0.30 to 0.60% Mn), which resulted in a shallower hardened zone after induction hardening.

It is more economical to use carbon steels whenever possible. The higher-manganese grades cost more than the lower-manganese grades, but are less expensive than the least expensive alloy grades.

Measuring Hardenability. Many tests have been proposed for measuring and comparing the hardenability of various grades of steel. The end-quench test (often referred to as the Jominy test) is used for testing the hardenability of carbon and alloy steels. This test involves heating a test bar 25.4 mm (1.0 in.) in diameter to the proper austenitizing temperature, placing the bar in a special hardenability fixture, and quenching only the end surface with water. Hardness is then measured along a plane just below the surface, at intervals of about 1.6 mm ($\frac{1}{16}$ in.) from the water-quenched end, to determine how far from this end the hardness extends. Typical end-quench hardenability data are given in the article "Hardenability Curves" in this Volume.

Some industries have found the SAC (surface area center) test, also known as the Rockwell inch test, to be more discriminating than the end-quench test for determining the hardenability of shallow-hardening steels because of the sharp gradient on the end-quench curve.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Carbon Steels Containing up to 0.25% C

Carbon steels with nominal carbon contents below about 0.25% are the first of three arbitrary classifications of carbon steels. Three principal types of heat treatments are used for this first group of steels:

- Case-hardening treatments, which are used mainly to produce a hard, wear-resistant surface layer
- Conditioning treatments, such as process annealing, that prepare the steel for certain fabricating operations
- Quenching and tempering to improve machinability

The improvements in mechanical properties that can be gained by the quenching and tempering of low-carbon steels, however, are minimal and are usually not worth the cost.

Many industrial applications require a part that is hard and wear resistant, but in almost every instance these properties are of prime importance at the surface of the part. Usually, it is a significant advantage in processing or service (or both) to have a part that is hard and wear resistant at the surface, yet softer, more ductile, and tougher below the surface. Case-hardening processes such as carburizing, carbonitriding, nitriding, and cyaniding are intended to produce just such a combination of properties by changing the composition of the surface layer through the absorption and inward diffusion of carbon, nitrogen, or both. Case hardening has very definite economic advantages for parts that must be formed and/or machined to intricate shapes and must be wear resistant in service, with surface properties approximating those normally attributed to high-carbon steels.

The cold-heading properties of most steels are improved by process annealing, spheroidizing, or stress relieving. In general, process annealing is done at the steel mill. Additional heat treatment is not used unless required, for at least two reasons: First, the process could cost more than any savings realized in cold heading, and, second, cold-headed products often depend for their final strength on work hardening prior to and during the heading process, and if reannealed before cold heading, they may lose much of their potential strength.

Heat treatments are frequently employed to improve machinability. The generally poor machinability of the low-carbon steels, except those containing sulfur or other special alloying elements, results principally from the fact that the proportion of free ferrite to carbide is high. This situation cannot be changed fundamentally, but the machinability can be improved by putting the carbide in its most voluminous form, pearlite, and dispersing this pearlite evenly throughout the ferrite mass. Normalizing is commonly used with success, but best results are obtained by quenching the steel in oil from a temperature of about 815 to 870 °C (1500 to 1600 °F). In steels other than 1025 and 1524, no martensite is formed, and the parts do not require tempering.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Carbon Steels Containing 0.25 to 0.55% C

Because of their higher carbon content, carbon steels containing 0.25 to 0.55% C are usually used in the hardened and tempered condition. By varying the quenching medium (cooling rate) and tempering temperature, a wide range of mechanical properties can be produced. These steels are the most versatile of the three groups of carbon steels and are most commonly used for crank-shafts, couplings, tie-rods, and many other machinery parts that have required hardness values in the range of 229 to 444 HB.

In this group of steels, which includes water-hardening and oil-hardening types, hardenability is very sensitive to changes in chemical composition, particularly to changes in the content of carbon, manganese, silicon, and residual elements. It is also sensitive to grain size. Figure 4 illustrates the general relationship between carbon content and hardness obtained in quenching for microstructures containing various amounts of martensite.

Fig. 4 Average relationship between carbon content and hardness for steels containing different amounts of untempered martensite in their microstructures

The rate of the heating of parts for quenching has a marked effect on hardenability under certain conditions. If the structure is nonuniform as a result of severe banding or lack of proper normalizing or annealing, extremely rapid heating (such as may be obtained in liquid baths) does not allow sufficient time for the diffusion of carbon and other elements in the austenite. Thus, nonuniform or low hardness will be produced unless the time at temperature is extended. In heating steels that contain free carbide (for example, spheroidized material), sufficient time must be allowed for the carbides to dissolve; otherwise, the austenite at the time of quenching will have a lower carbon content than is represented by the chemical composition of the steel, and disappointing results may be obtained. However, this condition may be produced deliberately (see the section "Carbon Steels Containing 0.55 to 1.00% C" below).

Usually these medium-carbon steels should be either normalized or annealed before hardening to obtain the best mechanical properties after hardening and tempering. Parts made from bar stock are frequently given no treatment prior to hardening, but it is common practice to normalize or anneal forgings.

Most bar stock, both hot finished and cold finished, is machined as received, except for the higher-carbon grades and small sizes that require annealing to reduce the as-received hardness. Forgings are usually normalized because this treatment avoids the extreme softening and consequent reduction of machinability that results from annealing.

In some instances, a cycle treatment is used. The parts are heated as for normalizing and are then cooled rapidly in the furnace to a temperature somewhat above the nose of the time-temperature transformation (TTT) curve, that is, within the transformation range that produces pearlite. The parts are then held at temperature or cooled slowly until the desired amount of transformation has taken place; thereafter, they are cooled in any convenient manner. Specially arranged furnaces are usually required. Details of the treatments vary widely and are frequently determined by the furnace equipment available.

Cold-headed products are commonly made from these steels, especially from those containing less than 0.40% C. Process treating before cold working is usually necessary because the higher carbon content decreases workability. For certain uses, these steels are normalized or annealed above the upper transformation temperature, but more frequently, a spheroidizing treatment is used. The degree of spheroidization required depends on the application. After shaping operations are finished, the parts may be heat treated by quenching and tempering.

These medium-carbon steels are widely used for machinery parts for moderate duty. When such parts are to be machined after heat treatment, the maximum hardness is usually held to 321 HB and frequently much lower.

Water is the quenching medium most commonly used because it is the most economical and the easiest to install. Caustic soda solution (5 to 10% NaOH by weight) is used in many instances with improved results. Compared to water, it is a faster and therefore a more thorough and uniform quench, producing better mechanical properties in all but light sections. Because of its rapid action, more scale is removed from the parts.

When used hot (55 to 70 °C, or 130 to 160 °F), caustic soda solution frequently makes possible drastic quenching of parts that could not be water quenched without cracking. The disadvantages of caustic soda are that it can be used only in a closed system with provisions made for cooling, operators must be protected against contact with it, the solution must be checked frequently, and the proper concentration must be maintained. Woolen clothing disintegrates rapidly after contact with it; cotton clothing is not affected.

Salt solutions (brine) are often successfully used. Up to about 40 °C (100 °F), they produce almost as good results as caustic solutions, but are much less effective when hot. Like caustic solutions, they require a closed system. Salt solutions are not as dangerous to operators as are hot caustic ones, but their corrosive action on iron and steel equipment is very serious.

When the section is thin or the properties required after heat treatment are not high, oil quenching is often used. This usually eliminates cracking and is very effective in reducing distortion.

Of the four quenching media, oil tends to provide the slowest cooling of steel parts, and brine the most rapid (Ref 2). Furthermore, the effectiveness of each of these liquids increases if it is agitated. Sometimes it is desirable to use a quenching medium with a severity between that of water and oil. For this, the so-called polymer quenchants are used. These include polyvinyl alcohol (PVA) (the most common), polyalkylene glycol ethers (PAGs), polyvinylpyrrolidone (PVP), and polyacrylates (Ref 2).

A wide range of austenitizing temperatures is necessary for compatibility with the possible variations in composition, grain size, section size, and quenching medium or cooling rate. Lower temperatures should be used for the higher-manganese steels, light sections, coarse-grained material, and water quenching; higher temperatures are required for lower-manganese steels, heavy sections, fine-grain materials, and oil quenching. Excessive temperatures should be avoided; in many steels, the higher austenitizing temperatures promote the retention of austenite.

Many common hand tools, such as pliers, open-end wrenches, screwdrivers, and a few edged tools (for example, tin snips and brush knives) are made from these steels. The cutting tools are necessarily quenched locally on the cutting edges, in water, brine, or caustic solution, and are subsequently given suitable tempering treatments. In some instances, the edge is time quenched; the remainder of the tool is then oil quenched for partial strengthening. When made of these grades of steel, pliers, wrenches, and screwdrivers are usually quenched in water, either locally or completely, and then are properly tempered.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Carbon Steels Containing 0.55 to 1.00% C

Carbon steels with these higher carbon contents are more restricted in application than are the 0.25 to 0.55% C steels because of decreased machinability, poor formability, and poor weldability, which make them more difficult and more costly to fabricate. They are also less ductile after hardening and tempering. Higher-carbon steels such as 1070 to 1095 are especially suitable for springs that require resistance to fatigue and permanent set. They are also used in the nearly fully hardened condition (55 HRC and higher) for applications in which abrasion resistance is a primary requirement, as for agricultural tillage tools such as plow-shares and knives for cutting hay or grain.

Forged parts should be annealed because the refinement of the forging structure is important in producing a high-quality hardened product and because the as-forged parts are too hard for cold trimming or for economical machining. Ordinary annealing practice, followed by furnace cooling to about 595 °C (1100 °F), is satisfactory for most parts.

Most of the parts made from steels in this group are hardened by conventional quenching. However, special techniques are necessary at times. Both oil and water quenching are used; water is used for heavy sections of the lower-carbon steels and for cutting edges, and oil is used for general purposes. Austempering and martempering are often applied successfully; the principal advantages from such treatments are considerably reduced distortion, elimination of breakage (in many instances), and greater toughness at high hardness.

For heavy machinery parts, such as shafts, collars, and the like, 1055 and 1561 steels may be used, either normalized and tempered for low strength or quenched and tempered for moderate strength. Other steels in the list may be used, but the combination of carbon and manganese in the two mentioned makes them particularly well adapted to such applications.

Even with favorable hardenability factors and with the use of a drastic quench, these steels are much shallower hardening than are alloy steels because carbon alone, or in combination with manganese in the amounts involved here, does not promote deep hardening. Therefore, the sections for which such steels are suited will definitely be limited. Even so, the danger of quench cracking is real and must be carefully guarded against when such parts are heat treated, especially parts of nonuniform section.

For hardening wrenches (except the Stillson type), screwdrivers, pliers, and similar tools, oil quenching is generally used, followed by tempering to the required hardness range. Even when no reduction of as-quenched hardness is desired, stress relieving at 150 to 190 °C (300 to 375 °F) is desirable to help prevent sudden service failures. In Stillson-type wrenches, the jaw teeth are really cutting edges and are nearly always quenched in water or brine to produce a hardness of 50 to 60 HRC. Either the jaws may be locally heated and quenched or the parts may be heated all over and the jaws locally time quenched in water or brine. The entire part is then quenched in oil for partial hardening of the remainder. In this way, considerable structural strength is obtained.

Hammers must possess high hardness on the striking face and somewhat lower hardness on the claws. They are usually locally hardened and tempered on each end, depending on type. The striking face is always quenched in water or brine. Satisfactory service depends on obtaining the proper depth of fully hardened (martensitic) surface on this face and then stress relieving at about 175 °C (350 °F). Final hardness is usually 50 to 58 HRC on the striking face and 40 to 47 HRC on claws.

Hand cutting tools, particularly axes and hatchets, must possess high hardness and high relative toughness in their cutting edges, as well as the ability to hold a keen edge. Because nothing is as effective as carbon in imparting the latter

property, the carbon content is always higher than if hardness and toughness alone were required. Many such tools are given an ordinary furnace anneal after forging, but high-quality tools are prepared for hardening by spheroidization, which may be performed as a separate operation after regular annealing. Most frequently, however, the spheroidizing and hardening treatment are combined by heating to 870 °C (1600 °F), quenching in oil, and then tempering at 675 to 745 °C (1250 to 1375 °F).

For hardening, the cutting edges of such tools are usually heated in liquid baths to the lowest temperature at which the piece can be hardened and are then quenched in brine. The quick heating of the liquid bath and the low temperature fail to put all the spheroidal carbide into solution. As a result, the cutting edge of the tool consists of martensite with less carbon than indicated by the chemical composition of the steel; it also contains particles of cementite. In this conditions, the tools is at its maximum toughness, relative to its hardness, and the cementite particles promote long life of the cutting edge. Final hardness may range from 55 to 60 HRC.

Agricultural Machinery Components. Manufacturers of agricultural implements make wide use of the steels in this group. Braces control rods, shafts, and similar parts are often made of high-carbon steels to obtain increased strength without the additional cost of heat treating. The principal heat-treated parts are plowshares, mold-boards, coulters, cultivator shovels, disks for harrows and plows, mower and binder knives, ledger plates, and band knives. Those parts used for cutting or turning soil must be moderately tough, with the ability to resist abrasion. They are made of steels containing various combinations of carbon and manganese that will permit full hardening.

Grass-cutting and grain-cutting tools are usually made of 1090 or 1095 steel because the higher carbon level provides the desired edge to give a long service life. These parts are made from strip stock by blanking. They are not annealed below the transformation range, except for some process annealing that may be done at the rolling mill. As a result, spheroidization is obtained only occasionally. Local hardening is done either by induction heating or in continuous furnaces provided with fixtures that permit the pieces to be heated on the cutting edges only. Upon discharge, the parts are quenched all over in oil and are tempered at a low temperature. Final hardness on the cutting edges may range from 55 to 60 HRC.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Alloy Steels

Alloy steels are ordinarily quench hardened and tempered to the level of strength desired for the application. The tempered martensite or bainite thus obtained imparts toughness, the capability of deforming without rupture.

The several elements commonly dissolved in austenite prior to quenching increase hardenability in approximately the following ascending order: nickel, silicon, manganese, chromium, molybdenum, vanadium, and boron. The addition of several alloying elements in small amounts is more effective in increasing hardenability than the addition of much larger amounts of one or two alloying elements.

To increase hardenability effectively, it is essential that the alloying elements be in solution in the austenite. Steels containing the carbide-forming elements, that is, chromium, molybdenum, and vanadium, require special consideration in this respect. These elements are present predominantly in the carbide form in annealed steels; such carbides dissolve only at higher temperatures, and dissolution proceeds more slowly than for iron carbide. Hence, for effectiveness, heating schedules should be set up to dissolve an adequate proportion of these elements. It is uneconomical to heat at such low temperatures that the carbide-forming elements are largely undissolved.

Because the basic function of alloying in these steels is to increase hardenability, the selection of a steel and the choice of suitable austenitizing conditions should primarily be based on obtaining adequate hardenability. More than adequate hardenability is rarely a disadvantage, except in terms of cost.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Alloying Elements in Quenching

Because the sections treated are often relatively large and because the alloying elements have the general effect of lowering the temperature range at which martensite is formed, the thermal and transformational stresses set up during quenching tend to be greater in these alloy steel parts than those encountered in quenching the necessarily smaller sections of plain carbon steels. In general, the greater stresses result in distortion and risk of cracking.

Alloying elements, however, have two functions that tend to offset these disadvantages. First and probably most important is the capacity to permit the use of a lower carbon content for a given application. The decrease in hardenability accompanying the decrease in carbon content may be readily offset by the hardenability effect of the added alloying elements, and the lower carbon steel will exhibit a much lower susceptibility to quench cracking. This lower susceptibility results from the greater plasticity of the lower-carbon martensite and from the generally higher temperature range at which martensite is formed in the lower-carbon materials. Quench cracking is seldom encountered in steel containing 0.25% C or less, and the susceptibility to cracking increases progressively with increasing carbon content.

The second function of the alloying elements in quenching is to permit slower rates of cooling for a given section because of increased hardenability, thereby generally decreasing the thermal gradient and, in turn, the cooling stress. It should be noted, however, that this is not altogether advantageous, because the direction, as well as the magnitude, of the stress existing after the quench is important in relation to cracking.

To prevent cracking, surface stresses after quenching should be either compressive or at a relatively low tensile level. In general, the use of a less drastic quench suited to the hardenability of the steel will result in lower distortion and greater freedom from cracking.

Furthermore, the increase hardenability of these alloy steels may permit heat treatment by austempering or martempering, and therefore the level of adverse residual stress before tempering may be held to a minimum. In austempering, the workpiece is cooled rapidly to a temperature in the lower bainite region and is held at that temperature so that the section transforms completely to bainite. Because transformation occurs at a relatively high temperature and proceeds rather slowly, the stress level after transformation is quite low, and distortion is minimal.

In martempering, the workpiece is cooled rapidly to a temperature just above M_s , held there until the piece attains a uniform temperature throughout, and then is cooled slowly (usually by air cooling) through the martensite range. This procedure causes martensite to form more or less simultaneously throughout the entire section, thereby holding transformational stresses at a very low level, which minimizes distortion and the danger of cracking.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Mechanical Properties

When quenched to martensite and tempered to the same hardness, carbon and alloy steels have similar tensile properties in that portion of the cross section that reacts to the quench. If carbon steel has the hardenability required by the critical section of the part and the quench used, the resulting tensile strength, yield strength, and elongation in the fully hardened zone will be in the same range as in a similar zone in an alloy steel quenched and tempered to the same hardness. The similarity in properties of the hardened zones is maintained, regardless of the depth of hardening, but the strength of the pieces will be governed by the thickness of the respective hardened zone (depth of hardening).

Figure 5 shows the relationship between hardness and tensile strength for hardened and tempered, as-rolled, annealed, or normalized carbon and alloy constructional steels. Because of the effect of cold working, this relationship may not apply to cold-drawn steels. Figure 6 shows the relation between tensile strength and yield strength. The effect of tempering temperature on tensile strength and hardness is shown in Fig. 7.

Fig. 5 Relation between tensile strength and Brinell hardness for steels in the as-rolled, normalized, or quenched and tempered condition. The tensile strength in ksi is approximately one-half the Brinell hardness number and in MPa is approximately $3\frac{1}{2}$ times the Brinell hardness number.

Fig. 6 Relation between tensile strength and yield strength for quenched and tempered steels. Source: Ref 1

Fig. 7 Effect of tempering temperature on tensile strength and hardness of hardened carbon and alloy steels with carbon contents of 0.50 and 0.30%

An important exception to this similarity of properties is the relationship between tensile strength and the reduction in area. Figure 8 shows the direct relationship between ductility and hardness and illustrates that the reduction in area decreases as hardness increases and, for a given hardness, the reduction is higher for alloy steels than for plain carbon steels. Figures 5, 6, 7, and 8 further reinforce the contention that, despite some differences in certain properties, the major difference between carbon and alloy steels is hardenability.

Fig. 8 Relation between tensile strength and the reduction in area for quenched and tempered steels

One other and sometimes important difference between carbon and alloy steels is that, for the same hardness levels, fully quenched alloy steels require higher tempering temperatures than do carbon steels. This higher tempering temperature is presumed to reduce the stress level in the finished parts without impairing mechanical properties.

Property relations given in Fig. 5, 6, 7, and 8 illustrate general correlations among mechanical properties of steels. Normal variations in composition and grain size from heat to heat and even within one heat produce a considerable scatter of results in sections of the same size.

Changes in section size have a greater influence on the mechanical properties of carbon steels (particularly when quenched and tempered) than on the properties of alloy steels because of the lower hardenability of carbon steels. The section size of a heat-treated section affects not only specific properties, but also the relation of one property to another. As the section size increases, incomplete response to hardening lowers the ratio of yield strength to tensile strength. Figure 9 shows mechanical property relations for 1030 steel in both the as-rolled and quenched and tempered conditions, as a function of section size. The tensile strength decreases as the section size increases for a given composition and heat treatment, and there is some lowering of the ratio of yield to tensile strength.

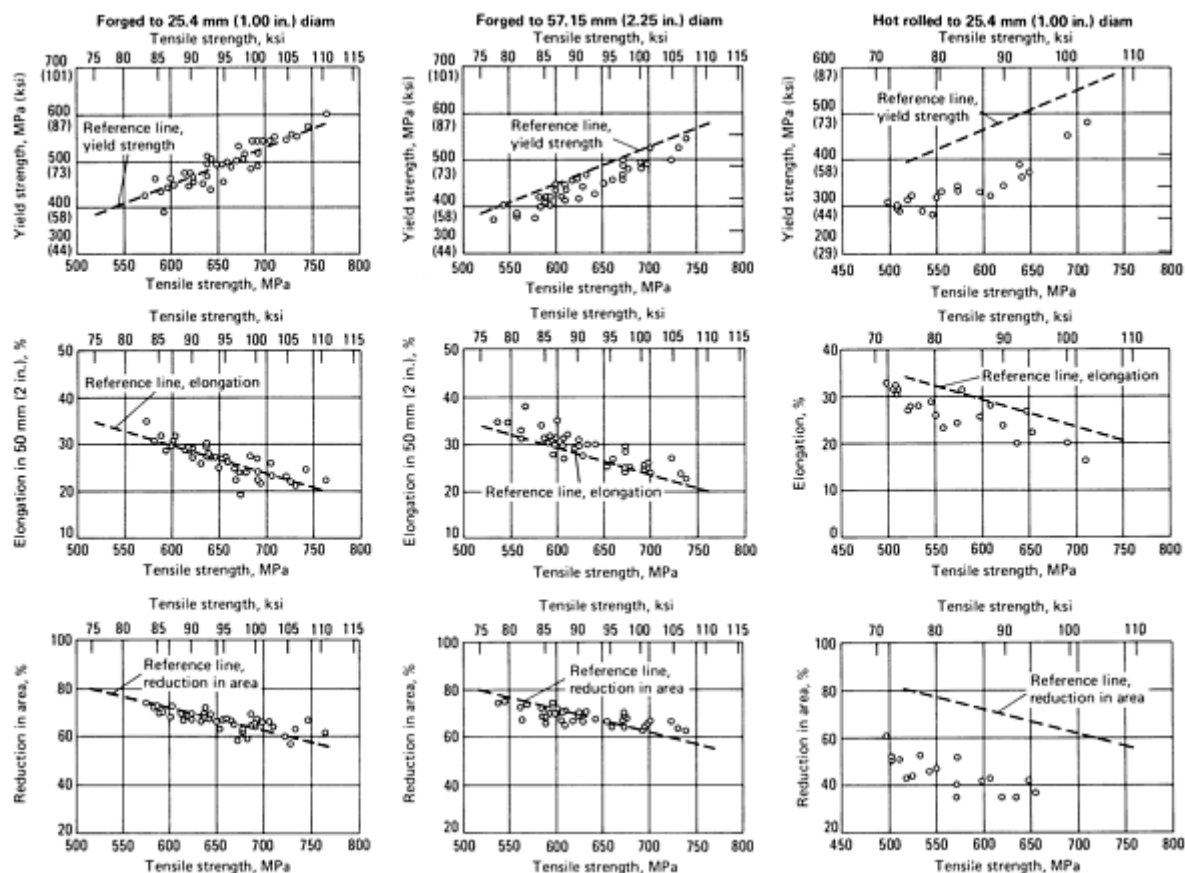

Fig. 9 Effect of processing variables on mechanical properties of 1030 steel. Billets of 1030 steel were either forged to 25 mm (1 in.) or 57.15 mm (2.25 in.) in diameter, then quenched and tempered, or they were hot rolled to 25 mm (1 in.) in diameter and not heat treated. Heat-treated specimens were water quenched from 870 °C (1600 °F) and tempered at 535 to 650 °C (1000 to 1200 °F). Specimens were taken from the center of 25 mm (1 in.) bars and at half-radius from the 57.15 mm (2.25 in.) bars. Reference lines represent mean values for the forged and heat-treated 25 mm (1 in.) diam bars.

As the section size increases and the hardness and strength levels increase, the hardenability of carbon steels is no longer adequate, and alloy steels must be used. The H-band alloy steels that should be considered for different design yield strength levels for highly stressed parts are given in Table 3 for round sections up to 102 mm (4 in.) in diameter. Either oil quenching or water quenching these alloys, as noted, should give 80% martensite at the indicated location within the section. For moderately stressed parts, a 50% martensite structure at the center is frequently adequate. The H-band alloy steels that can produce 50% martensite at the indicated location by oil or water quenching are given in Table 4 for round sections up to 102 mm (4 in.) in diameter. This information is intended to be a guide in the selection of an appropriate alloy steel; variations in equipment and techniques will greatly influence the final properties obtained. The grades are listed in the approximate order of increasing alloy cost to further aid in the initial screening of candidate alloys.

Table 3 Alloy steel selection guide for highly stressed parts

Unless otherwise indicated in the footnotes, any steel in this table may be considered for a lower strength level or a smaller section, or both.

Increasing carbon content consistently increases tensile and yield strength and decreases elongation and reduction in area, regardless of whether the steel is as-rolled or quenched and tempered (provided the ranges of tempering temperatures are the same). However, there is one major disadvantage to increasing the carbon content: Carbon steels show an increasing tendency to crack on quenching as the carbon content increases above about the 0.35% level. Consequently, parts to be made from steel having a carbon content greater than 0.35% should be tested for quench cracking before production is begun.

Variations in chemical composition within a specific grade contribute to the scatter of mechanical properties. This is illustrated by the test data in Fig. 10, where the properties for two heats of quenched and tempered 1050 steel are compared for a tempering range of 315 to 650 °C (600 to 1200 °F).

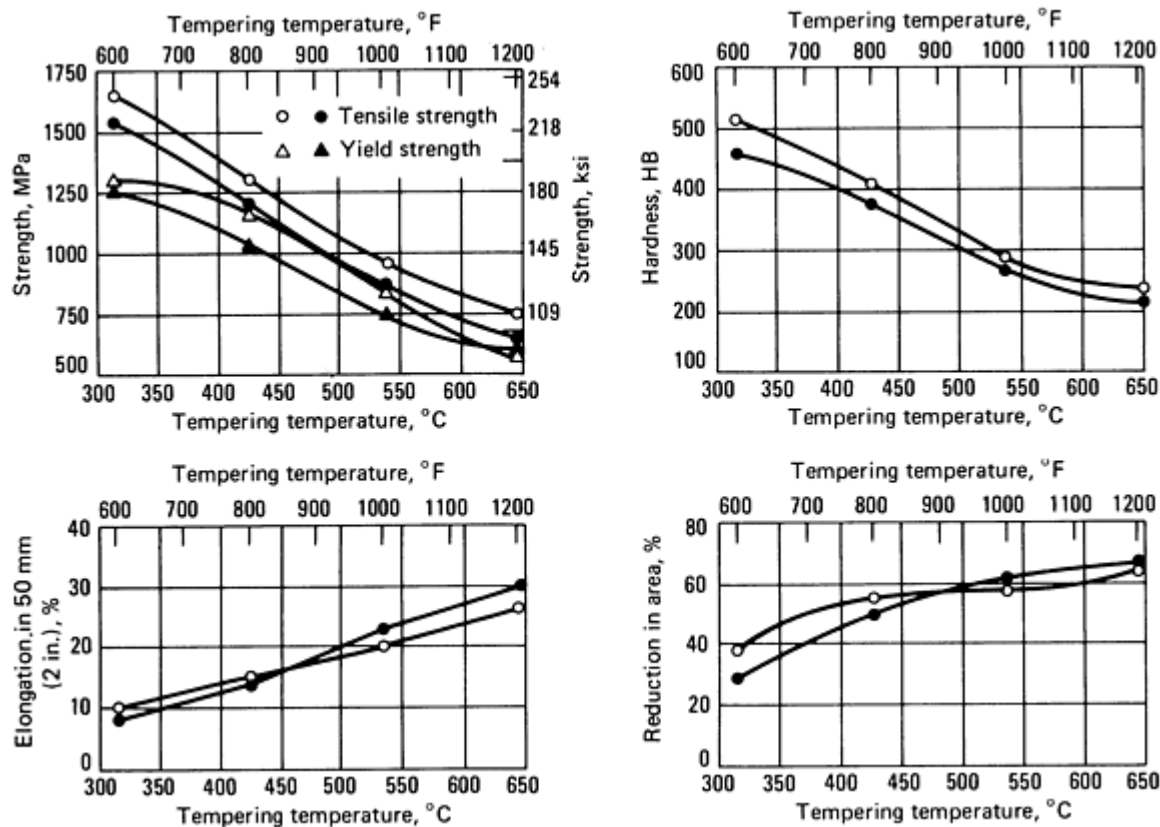

Fig. 10 Effect of composition and tempering temperature on mechanical properties of 1050 steel. Properties are summarized for two heats of 1050 steel that was forged to 38 mm (1.50 in.) in diameter, then water quenched and tempered at various temperatures. Open symbols are for heats containing 0.52 C and 0.93 Mn; closed symbols, for those containing 0.48 C and 0.57 Mn.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Tempering

Hardened steels are softened by reheating, although this effect may not be sought in tempering. The real need is to increase the capability of the steel to flow moderately without fracture, and this is inevitably accompanied by a loss of strength. The tensile strength is very closely related to hardness in this class of steels, as heat treated; thus, the effects of tempering can be followed by measuring the Brinell or Rockwell hardness.

Figure 11 shows the response to tempering of four carbon and alloy steels containing 0.45% C. All steels were tempered for 1 h at the temperatures indicated. Somewhat shorter or longer intervals at temperature would affect hardness values to various degrees, depending on the tempering temperature.

Fig. 11 Tempering characteristics of four 0.45% carbon and alloy steels tempered for 1 h

The general effect of alloying is to retard the tempering rate, and therefore alloy steels require a higher tempering temperature to obtain a given hardness than does carbon steel of the same carbon content. However, the individual elements show significant differences in the magnitude of their retarding effect. Nickel, silicon, aluminum, and, to a large extent, manganese, all of which have little or no tendency to occur in the carbide phase and merely remain dissolved in ferrite, have only a minor effect on the hardness of the tempered steel, as would be expected from the general pattern of solid-solution hardening.

However, the carbide-forming elements, chromium, molybdenum, and vanadium, retard softening, particularly at higher tempering temperatures. These elements do not merely raise the tempering temperature; when they are present in higher percentages, the rate of tempering is no longer a continuous function of tempering temperature. That is, the tempering curves for these steels will show a range of tempering temperature in which the tempering is retarded or, with relatively high alloy content, in which the hardness may actually increase with an increase in tempering temperature. This characteristic behavior is known as secondary hardening and results from a delayed precipitation of fine alloy carbides. Secondary hardening is most often encountered in the higher-alloy tool steels.

As mentioned previously, the primary purpose of tempering is to impart plasticity or toughness to the steel, and the loss in strength is only incidental to this very important increase in toughness. The increase in toughness after tempering reflects two effects of tempering:

- The relief of residual stress induced during quenching
- The precipitation, coalescence, and spheroidization of iron and alloy carbides, resulting in a microstructure of greater plasticity

In addition to their effects on microstructure, the alloying elements have a secondary function. The higher tempering temperatures for a given hardness, which has been determined to be characteristic of alloy steels (particularly those containing carbide-forming elements), will presumably permit greater relaxation of residual stress and thereby improve properties. Furthermore, as discussed in the section "Alloying Elements in Quenching" in this article, the hardenability of these steels may permit the use of less drastic quenching practices, so that the stress level before tempering will be lower, permitting these steels to be used at a higher level of hardness; this is because higher temperatures are not required for relief of quenching stresses. It should be noted, however, that this latter characteristic is only a secondary function of alloying elements in tempering; the effect primarily reflects the hardenability function of the alloying elements.

Another secondary function of alloying elements in tempering is to permit the use of steels with lower carbon content for a given level of hardness, because adequate tempering may be ensured by the retardation of softening caused by alloying. This results in greater freedom from cracking and generally improved plasticity at any given hardness. Here again, the function of alloying elements in tempering is a secondary function; their primary function is to increase hardenability sufficiently to offset the effect of a decreased carbon content.

The increase in plasticity upon tempering is discontinuous in those alloy steels that contain the carbide-forming elements; the behavior of notched specimens shows a characteristic irregularity at approximately 260 to 315 °C (500 to 600 °F). The quenched martensitic steel gains toughness, as reflected in a notched-bar impact test, by tempering at temperatures as high as 205 °C (400 °F). However, after tempering at higher temperatures, in the temper-brittle range, these types of steel lose toughness until they may be less tough than the same steels not tempered. Still higher tempering temperatures restore greater toughness (see Fig. 12).

Fig. 12 Hardness and notch toughness of 4140 steel tempered for 1 h at various temperatures

The mechanism of this behavior is not fully understood, but it seems to be associated with the first precipitation of carbide particles and is presumably a grain boundary phenomenon; fractures of steels tempered in this region tend to follow intergranular paths. Thus, there is a range of tempering temperatures at about 205 to 370 °C (400 to 700 °F) never used for these steels; the tempering temperature is either below 205 °C (400 °F) or above 370 °C (700 °F). Although this phenomenon is common to all of these alloy steels, the alloying elements have a secondary function in this connection; a combination of carbon and alloy contents of suitable hardenability may be chosen that would permit tempering to the desired strength at temperatures outside this undesirable range.

Temper brittleness is another example of a discontinuous increase in plasticity subsequent to the tempering of steels containing the carbide-forming elements. This phenomenon is manifested as a loss of toughness, observed after slow cooling from tempering temperatures of 575 °C (1070 °F) or higher or after tempering in the temperature range between approximately 375 and 575 °C (700 and 1070 °F). Thus, a steel that is susceptible to temper embrittlement may lose much of its plasticity, as indicated by a notched-bar impact test, during slow cooling from a high tempering temperature, although the same steel will be very tough if it is quenched from the same tempering temperature. This expedient of quenching from the tempering temperature is often overlooked as a practical means for avoiding severe temper embrittlement in susceptible steels tempered at 575 °C (1070 °F) or higher. In steels susceptible to temper brittleness, embrittlement will also be observed after tempering at 375 to 575 °C (700 to 1070 °F), particularly if the tempering times are protracted. Under such circumstances, quenching from the tempering temperature will never restore the toughness.

High manganese, phosphorus, and chromium concentrations appear to accentuate the embrittling reaction; molybdenum has a definite retarding effect. Here again, the carbon and alloying elements may be chosen so that the susceptibility to temper embrittlement is minimized or the desired strength level is obtained by tempering either below 375 °C (700 °F) or

above 575 °C (1070 °F) and then quenching. Temper brittleness is discussed in greater detail in the article "Embrittlement of Steels" in this Volume.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Distortion in Heat Treatment

Distortion during heat treatment may occur with almost any hardenable carbon or alloy steel, although distortion is usually more severe for carbon grades than for alloy grades of equivalent carbon content. Carbon steels distort more than alloy steels mainly because carbon steels require a water or brine quench to develop full hardness (at least in sections thicker than about 9.5 mm, or $\frac{3}{8}$ in.). This often eliminates carbon steels from consideration for critical parts.

This distortion may be observed as a change in dimensions (size distortion) or a change in configuration or contour (shape distortion or warpage), or both. A more complete discussion of these types of distortion and the factors that influence them may be found in Ref 4, 5, and 6.

Several factors contribute to the total distortion that occurs during heat treatment. These include residual stresses that may be present as a result of machining or other cold-working operations, the method of placing in the furnace, the rate of heating, nonuniform heating, and the normal volumetric changes that occur with phase transformations. However, the most important, single factor is uneven cooling during quenching, caused mainly by the configuration and by changes in cross-sectional area. Symmetrical parts with little or no variation in section may have almost no distortion, whereas complex parts with wide variations in section may distort so much that they cannot be used (or at least so much that they require excessive finishing operations to make them suitable for use).

Other factors being equal, the distortion in carbon steels will increase as the carbon content increases because of the gradual lowering of the martensite start (M_s) temperature with increasing carbon. There is also a significant variation in the magnitude of distortion and direction of dimensional change among different heats of the same grade of steel, even though other variables are minimal. This happens because of several factors, including minor variations in composition and grain size, but mainly because of the history of the steel with regard to hot working, cold working, and heat treatment.

Because of the different variables that contribute to total distortion, the prediction of distortion in actual parts is seldom reliable if it is based on the behavior of small test pieces. The most practical approach is to make studies on pilot lots of actual pieces that have been heat treated under production conditions. This procedure eliminates the shape variable so that the direction and magnitude of distortion can be plotted as ranges that incorporate most of the other variables. After a quantity of such data has been secured, a series of guideposts is established, and it becomes possible to predict distortion for similar parts made from the same steel grade with reasonable accuracy. However, it must be emphasized that any such study is accurate only when many parts made from different heats supplied by several mills are included.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Induction and Flame Hardening

The relatively low hardenability of carbon steels is often a primary reason for choosing them in preference to alloy steels for parts that are to be locally heat treated by flame or induction hardening. One of the oldest rules for selecting steels for heat treating is to choose grades that are no higher in carbon or alloy content than is essential to develop required properties. This rule remains valid in the selection of steels to be heat treated by induction or flame processes.

When the peripheries of steel parts are heated rapidly and quenched, the tendency to crack depends mainly on a combination of four factors:

- Final surface hardness
- Temperature to which the surface has been heated
- Uniformity of heating
- Depth of hardened zone

The optimum heat pattern for either induction or flame heating depends on the type of steel and on the mass and shape of the part. The ideal heat pattern for any specific part will provide a hardened shell to a depth that will strengthen the part by establishing a favorable stress pattern. However, if the hardened zone is too deep for the specific section thickness, high tensile stresses are established in the surface layers, and these may either cause cracking or adversely affect service life.

Excessive depth of the hardened zone can be caused by improper processing (overheating, for instance) or by the choice of a steel with excessive hardenability. However, excessive carbon can aggravate other contributing factors and become the basic cause for cracking. The M_s temperature decreases as the carbon content increases. It is lowered further by higher austenitizing temperatures. In general, as the M_s temperature is lowered, the probability of surface cracking increases.

Hardenable Carbon and Low-Alloy Steels

Revised by Eugene R. Kuch, Gardner Denver Division of Cooper Industries

Fabrication of Parts and Assemblies

Fabrication processes are usually performed on hardenable carbon and alloy steels in the unhardened condition, that is, prior to heat treating. This is done primarily to avoid the high cost and difficulty of fabrication that are characteristic of high-strength materials. However, even in the unhardened condition, there are differences among the various grades in respect to formability, weldability, machinability, and forgeability properties. In many instances, difficulties arising during the fabrication of a given hardenable steel are directly related to the maximum hardness that can be developed and to hardenability.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Introduction

HARDENABILITY OF STEEL is the property that determines the depth and distribution of hardness induced by quenching. Steels that exhibit deep hardness penetration are considered to have high hardenability, while those that exhibit shallow hardness penetration are of low hardenability. Because the primary objective in quenching is to obtain satisfactory hardening to some desired depth, it follows that hardenability is usually the single most important factor in the selection of steel for heat-treated parts.

Hardenability should not be confused with hardness as such or with maximum hardness. The maximum attainable hardness of any steel depends solely on carbon content. Also, the maximum hardness values that can be obtained with small test specimens under the fastest cooling rates of water quenching are nearly always higher than those developed under production heat-treating conditions, because hardenability limitations in quenching larger sizes may result in less than 100% martensite formation. The effects of carbon and martensite content on hardness are shown in Fig. 1. Basically, the units of hardenability are those of cooling rate, for example, degrees per second. These cooling rates, as related to the continuous-cooling-transformation behavior of the steel, determine the hardness and microstructural outcome of a quench. In practice, these cooling rates are often expressed as a distance, with other factors such as the thermal conductivity of steel and the rate of surface heat removal being held constant. Therefore, the terms Jominy distance and ideal critical diameter can be used.

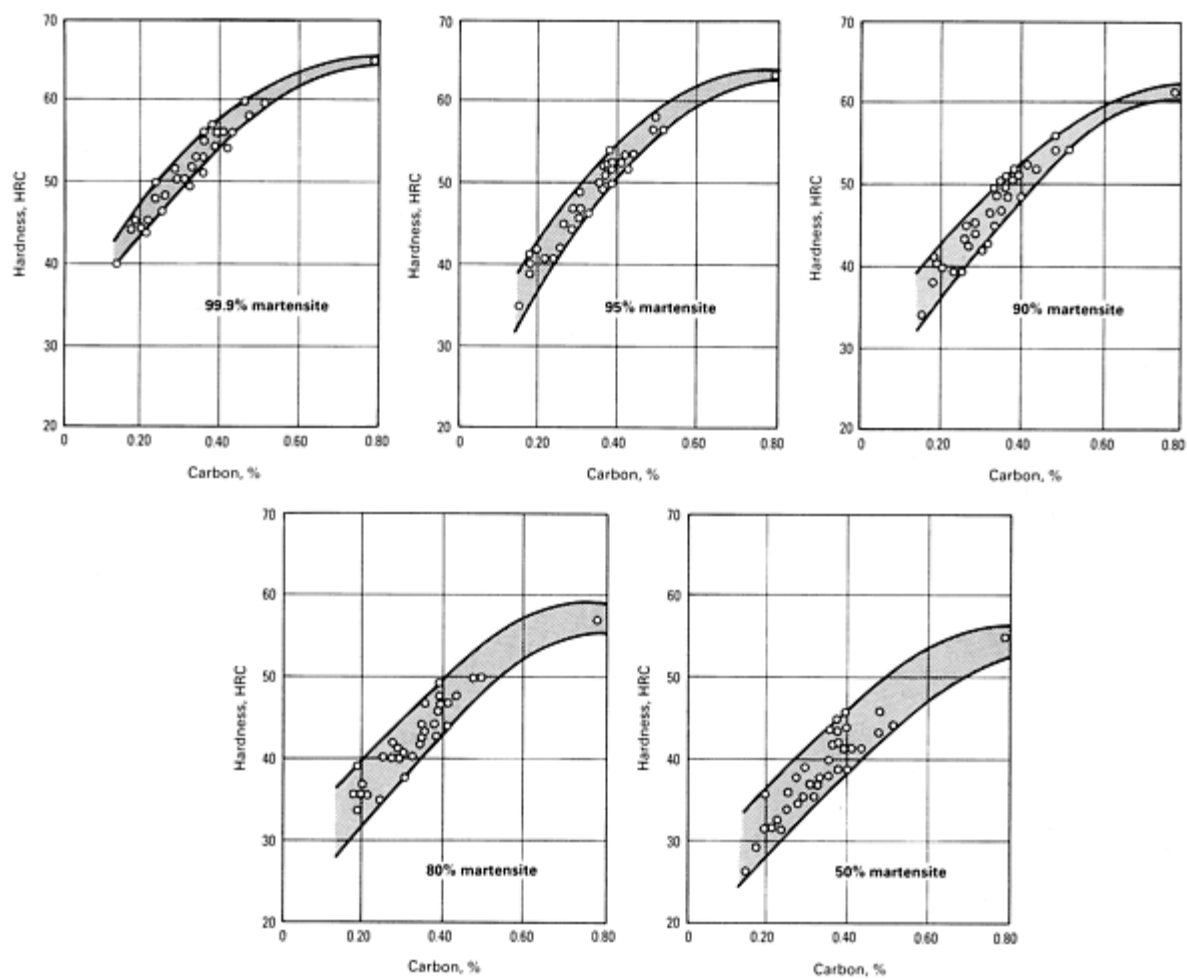

Fig. 1 Effect of carbon on the hardness of martensite structures

The hardenability of steel is governed almost entirely by the chemical composition (carbon and alloy content) at the austenitizing temperature and the austenite grain size at the moment of quenching. In some cases, the chemical composition of the austenite may not be the same as that determined by chemical analysis, because some carbide may be undissolved at the austenitizing temperature. Such carbides would be reflected in the chemical analysis, but because the carbides are undissolved in the austenite, neither their carbon nor alloy content can contribute to hardenability. In addition, by nucleating transformation products, undissolved carbides can actively decrease hardenability. This is especially important in high-carbon (0.50 to 1.10%) and alloy carburizing steels, which may contain excess carbides at the austenitizing temperature. Consequently, such factors as austenitizing temperature, time at temperature, and prior microstructure are sometimes very important variables when determining the basic hardenability of a specific steel composition. Certain ingot casting and hot reduction practices may also develop localized or periodic inhomogeneities within a given heat, further complicating hardenability measurements. The effects of all these variables are discussed in this article.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Hardenability Testing

The hardenability of a steel is best assessed by studying the hardening response of the steel to cooling in a standardized configuration in which a variety of cooling rates can be easily and consistently reproduced from one test to another.

The Jominy end-quench test fulfills the cooling rate requirements of hardenability testing of a broad range of alloy steels. The test specimen, a 25.4 mm (1.000 in.) diam bar 102 mm (4 in.) in length, is water quenched on one end face. The bar from which the specimen is made must be normalized before the test specimen is machined. The test involves heating the test specimen to the proper austenitizing temperature and then transferring it to a quenching fixture so designed that the specimen is held vertically 12.7 mm (0.5 in.) above an opening through which a column of water can be directed against the bottom face of the specimen (Fig. 2a). While the bottom end is being quenched by the column of water, the opposite end is cooling slowly in air, and intermediate positions along the specimen are cooling at intermediate rates. After the specimen has been quenched, parallel flats 180° apart are ground 0.38 mm (0.015 in.) deep on the cylindrical surface. Rockwell C hardness is measured at intervals of $\frac{1}{16}$ in. (1.6 mm) for alloy steels and $\frac{1}{32}$ in. (0.8 mm) for carbon steels, starting from the water-quenched end. A typical plot of these hardness values and their positions on the test bar, as shown in Fig. 2(b), indicates the relation between hardness and cooling rate, which in effect is the hardenability of the steel. Figure 2(b) also shows the cooling rate for the designated test positions. Details of the standard test method are available in ASTM A 255 and SAE J406.

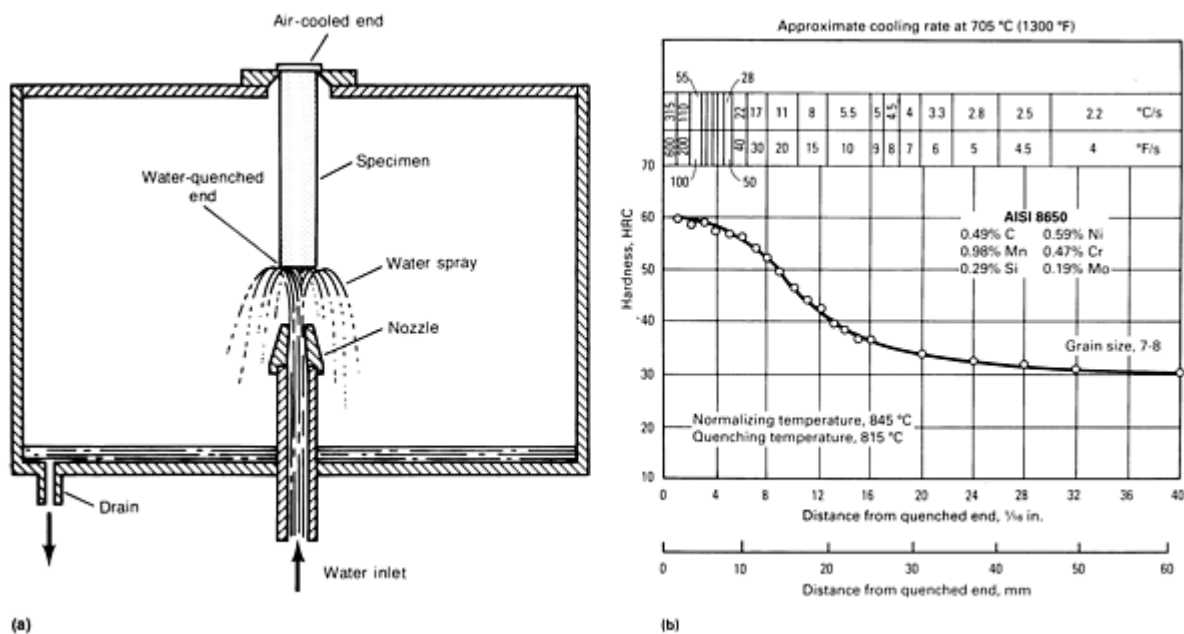

Fig. 2 Jominy end-quench apparatus (a) and method for presenting end-quench hardenability data (b)

The Carburized Hardenability Test. It is often necessary to determine the hardenability of the high-carbon case regions of carburized steels. Such information is important in controlling carburizing and quenching practice and in determining the ability of a specific steel to meet the microstructural and case depth requirements of the carburized component manufactured from the steel. As a general rule, adequate core hardenability does not ensure adequate case hardenability, especially when it is required to reheat for hardening after carburizing rather than to quench directly from the carburizing furnace. Two factors are responsible for this fact. The first is that equal alloying additions do not have the same effect on the hardenability of all carbon levels of alloyed steels. The second factor (as noted earlier) is that the high-carbon case regions do not always achieve full solution of alloy and carbides, as is normally achieved in the austenite of the low-carbon core region, prior to quenching. Accordingly, direct measurements of case hardenability are very important whenever a carburizing steel must be selected for a specific application.

Measurements of case hardenability are performed as follows. A standard end-quench bar is pack carburized for 9 h at 925 °C (1700 °F) and end quenched in the usual manner. A comparison bar is simultaneously carburized in the same pack to determine carbon penetration. Successive layers are removed from it and analyzed chemically to determine the carbon content at various depths. When a carbon-penetration curve is established, depths to various carbon levels can be determined in the Jominy bar, assuming that the distribution of carbon in the end-quench specimen is the same as in the carbon gradient bar. Longitudinal flats are then carefully ground to various depths on the end-quench bar (usually to carbon concentrations of 1.1, 1.0, 0.9, or 0.8%, and in some cases to as low as 0.6%), and hardenability is determined at these carbon levels by hardness traverses. In grinding, care must be exercised to avoid overheating and tempering, and in

conducting hardness surveys, similar concern must be shown to ensure that the hardness level corresponds to a single carbon level by remaining in the exact center of the flat. Rockwell A hardness readings are preferable to Rockwell C readings because they minimize the depth of indenter penetration into softer subsurface layers. Rockwell A values are converted into Rockwell C values for plotting, as illustrated in Fig. 3, which shows the curves of carburized hardenability of an EX19 steel. In the higher-carbon layers of carburized specimens, the hardness will be influenced by the presence of retained austenite. Therefore, it is often useful to evaluate the microstructure/depth relationship by metallographically polishing and etching the ground flats. The Jominy distance to some chosen level of nonmartensitic transformation product can then be used as a measure of hardenability.

Fig. 3 Carburized hardenability, EX19 steel. Composition: 0.18 to 0.23% C, 0.90 to 1.20% Mn, 0.40 to 0.60% Cr, 0.08 to 0.15% Mo, 0.0005% B (min)

The case hardenability of steels that are carburized and then reheated for hardening at temperatures below 925 °C (1700 °F), such as 8620, 4817, and 9310, can also be determined by using a modification of this technique. The carburized end-quench specimens and companion gradient bars are oil quenched together from carburizing, but are then reheated in an atmosphere furnace to the desired austenitizing temperature for a total of 55 to 60 min, which should ensure at least 30 to 35 min at temperature. The hardenability specimen is then end quenched, and the carbon gradient bar is oil quenched and tempered to facilitate machining for carbon gradient determination, as described above. It is recommended that case hardenability tests be performed on no fewer than two test specimens. A more detailed description of the case hardenability measurement technique appears in SAE J406.

Air Hardenability Test. Occasionally, the hardening performance either of a steel cooled at a rate slower than that applied to the end-quench bar or of steels of very high hardenability must be determined. An air hardenability test method described in Ref 1 can be employed for this purpose. In this test, a machined and partially threaded round test specimen, 25.4 mm (1.000 in.) in diameter and 254 mm (10 in.) long, is inserted to a depth of 152 mm (6 in.) in a hole drilled in a bar 152 mm (6 in.) in diameter and 381 mm (15 in.) long, thus leaving 102 mm (4 in.) of the test bar length exposed (Fig. 4). A second test specimen can be inserted at the opposite end of the bar holder to serve as a duplicate. With both test bars securely in place, the assembly is heated to the proper austenitizing temperature, after which it is transferred to a convenient location for cooling in still air. This cooling procedure results in very slow and ever decreasing cooling rates

along the length of the test bars. Hardness is then measured at discrete intervals along each test bar and plotted against distance from the exposed end on charts specifically designed for this purpose.

Fig. 4 Dimensions (given in inches) of components in air hardenability test setup

Continuous-Cooling-Transformation Diagrams. The use of continuous-cooling-transformation diagrams determined dilatometrically, for example, can also be helpful in evaluating the cooling behavior of high-hardenability steels.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Low-Hardenability Steels

In plain carbon and very low-alloy steels, the cooling rate at even the 1.6 mm ($\frac{1}{16}$ in.) position on a standard Jominy bar may not be fast enough to produce full hardening. Therefore, this test lacks discrimination between these steels. Tests that are more suited to very low hardenability steels include the hot-brine test and the surface-area-center (SAC) test.

In the hot-brine test proposed by Grange, coupons (Fig. 5) are quenched in brine maintained at a series of different temperatures. As shown in Fig. 6, the resulting hardnesses provide a very sensitive test of hardenability.

(a)

(b)

Fig. 5 Hot-brine hardenability test specimen. (a) Specimen dimensions. (b) Method of locating hardness impressions after heat treatment. Dimensions given in millimeters. Source: Ref 2

Fig. 6 Typical results of the hot-brine hardenability test. Steel composition: 0.18% C, 0.81% Mn, 0.17% Si, and 1.08% Ni. Austenitized at 845 °C (1550 °F). Grain size: 5 to 7. RT, room temperature. Source: Ref 2

In the SAC test, a 25.4 mm (1.000 in.) round bar is normalized by cooling in air and then reaustenitized for water quenching. Hardnesses are measured on a specimen cut from the center of the 100 mm (4 in.) length. Hardness is determined on the surface, the center, and at 1.6 mm ($\frac{1}{16}$ in.) intervals from surface to center. An area hardness is then computed as the sum of the average hardness in each interval $\times \frac{1}{16}$ (Fig. 7). The resulting set of three-digit numbers, for example, SAC No. 63-52-42, indicates a surface hardness of 63 HRC, a Rockwell-inch area of 52, and a center hardness of 42 HRC. Testing details are given in SAE J406.

S = average surface hardness
 h_1, h_2, h_3 , and so on = average hardness at depths indicated
 C = average center hardness

$$\text{Then area of } A = \frac{S + h_1}{2} \times \frac{1}{16}$$

$$\text{Area of } B = \frac{h_1 + h_2}{2} \times 4 \times \frac{1}{16}$$

$$\begin{aligned}
 \text{Total area} &= 2(A + B + C + D + E + F + G + K) \\
 &= \frac{1}{8} \left(\frac{S}{2} + h_1 + h_2 + h_3 + h_4 + h_5 + h_6 + h_7 + \frac{C}{2} \right)
 \end{aligned}$$

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Calculation of Hardenability

The hardenability of a steel is primarily a function of the composition (carbon, alloying elements, and residuals) and the grain size of the austenite at the instant of quenching. If this relationship can be determined quantitatively, it should be possible to predict the hardenability of a steel through a relatively simple calculation.

Such a technique was published by Grossmann in 1942, based on his observation that hardenability could be expressed as the product of a series of composition-related multiplying factors (Ref 3). The result of the calculation is an estimate of D_i , the ideal critical diameter of the steel. The multiplying-factor principle is still used today in several hardenability calculation techniques (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume for examples of multiplying factors for quench and tempered low-alloy steels). Other researchers have developed methods based on regression equations and on calculation from thermodynamic and kinetic first principles. To date, none of the hardenability prediction methods has proved to be universally applicable to all steel types; that is, different predictors are more suited to steels of given alloying systems, carbon contents, and hardenability levels. In addition, it is often necessary to fine-tune the predictions based on the characteristics (residuals, melt practice, and so on) of a particular steel producer. Some excellent discussions of current thinking on this subject are available in Ref 4 and 5. Properly used, hardenability calculations can provide a valuable tool for designing cost-effective alternative steels, for deciding the disposition of heats in the mill prior to rolling, and possibly for replacing the costly and time-consuming measurement of hardenability.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Effect of Carbon Content

Carbon has a dual effect in hardenable alloy steels: It controls maximum attainable hardness and contributes substantially to hardenability. The latter effect is enhanced by the quality and type of alloying elements present. It might be concluded, therefore, that increasing the carbon content is the least expensive approach to improving hardenability. This is true to a degree, but several factors weigh against the use of large amounts of carbon:

- High carbon content generally decreases toughness at room and subzero temperatures
- It produces harder and more abrasive microstructures in the annealed conditions, which makes cold shearing, sawing, machining, and other forms of cold processing more difficult
- It makes the steel more susceptible to hot shortness in hot working
- It makes the steel more prone to cracking and distortion in heat treatment. Because of these disadvantages, more than 0.60% C is seldom used in steels for machine parts, except for springs and bearings, and steels with 0.50 to 0.60% C are used less frequently than those containing less than 0.50% C

Figure 8 shows the differences between minimum hardenability curves for six series of steels. In each series, alloy content is essentially constant, and the effect of carbon content on hardenability can be observed over a range from 0.15 to 0.60%. The hardness effect is shown by the vertical distance between the curves at any position on the end-quench specimen, that is, for any cooling rate. This effect varies significantly, depending on the type and amounts of alloying elements. For example, referring to Fig. 8 (d) to (f), an increase in carbon content from 0.35 to 0.50% in each of the three series of steels causes hardness increases (in Rockwell C points) at four different end-quench positions, as shown below:

Series	Distance from quenched surface, in.			
	$\frac{1}{16}$	$\frac{4}{16}$	$\frac{8}{16}$	$\frac{12}{16}$
41xxH	8	10	17	20
51xxH	8	13	9	8
86xxH	8	12	18	12

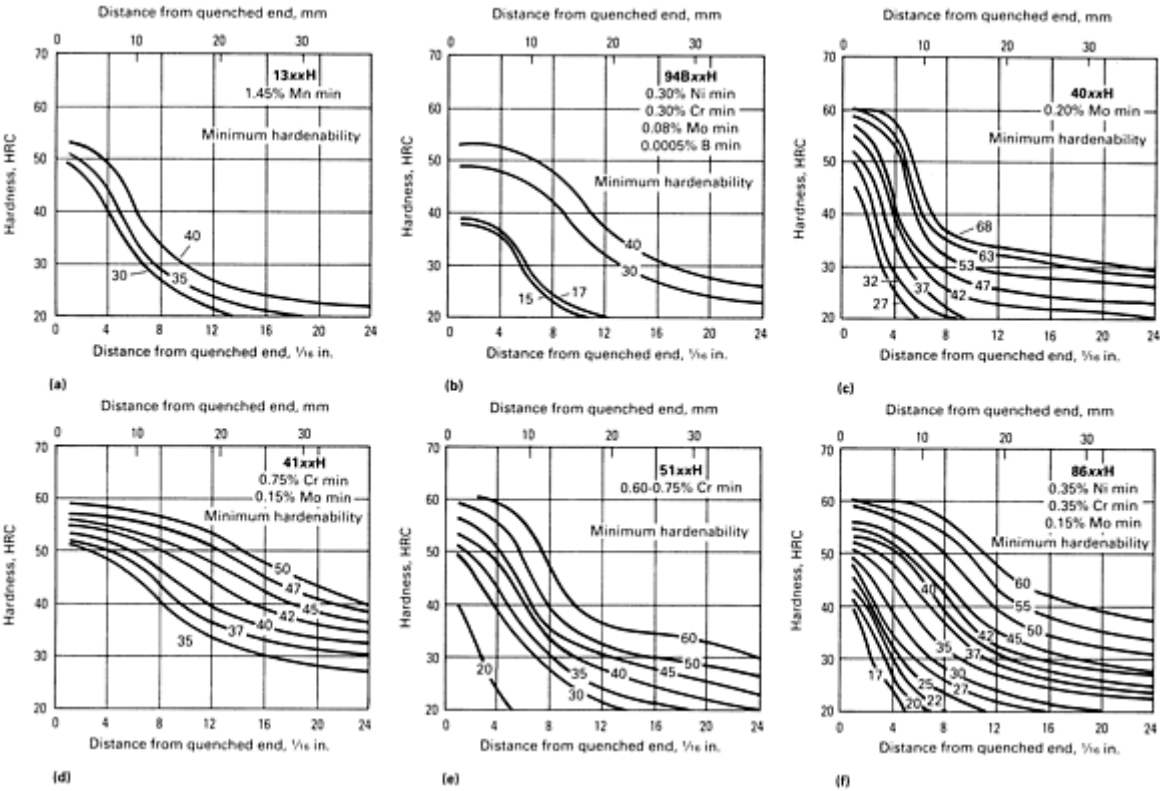

Fig. 8 Effect of carbon content on the minimum end-quench hardenability of six series of alloy H-steels. The number adjacent to each curve indicates the carbon content of the steel, to be inserted in place of xx in alloy designation.

The hardenability effect of carbon content is read on the horizontal axis in Fig. 8. If the inflection points of the curves are used to approximate the position of 50% martensite transformation, the effect of carbon content on hardenability in 8650 versus 8630 steel can be expressed as $+\frac{4}{16}$; that is, the inflection point is moved from the $\frac{5}{16}$ position to the $\frac{9}{16}$ position. Similarly, with nominal carbon contents of 0.35 and 0.50%, the hardenability effect of carbon is seen to be less ($\frac{2}{16}$) in 51xx series steels and more ($\frac{6}{16}$) in 41xx steels.

Considering the combined hardening and hardenability effects in terms of quenching speed, the cooling rate (or quenching speed) required to produce 45 HRC is affected more by 0.15% C with certain combinations of alloying elements than it is by other combinations. For example, in a steel containing 0.75 Cr and 0.15 Mo (a 41xxH series steel, for example), increasing the carbon content by 0.15% lowers the required or critical cooling rate to obtain 45 HRC from 25 to 4.6 °C (45 to 8.3 °F) per second, while in a steel containing 0.75% Cr and no molybdenum (51xxH series), the same increase in carbon content lowers the cooling rate from 47 to 21 °C (85 to 37 °F) per second.

The practical significance of the effect of carbon and alloy contents on cooling rate is considerable. In a 51 mm (2 in.) diam bar of 4150 steel, a hardness of 45 HRC can be obtained at half-radius using an oil quench without agitation. In a 4135 steel bar of the same diameter, to obtain the same hardness at half-radius would require a strongly agitated water quench. Comparing 32 mm ($1\frac{1}{4}$ in.) diam bars of 5135 and 5150 steel, an agitated water quench will produce a hardness of 45 HRC at half-radius in the 5135 bar; the identical condition can be obtained in the 5150 bar using an oil quench with moderate agitation. Thus, an increase or decrease in carbon content or an alloying addition, such as 0.15% Mo, affects the results obtained both in terms of the quenching severity required and the section size in which the desired results can be obtained.

Figure 9 shows how steels are rated on the basis of ideal critical diameter by expressing the effect of carbon and alloy content on the section size that will harden to 50% martensite at the center, assuming an ideal quench. An ideal quench is defined as one that removes heat from the surface of the steel as fast as it is delivered to the surface. In general, the relation between hardness and carbon content that is important in practice is obscured in this rating method because the steel is rated to a constant microstructure. Hardness decreases continuously with lower carbon contents.

Fig. 9 Effect of carbon content on ideal critical diameter, calculated for the minimum chemical composition of each grade

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Alloying Elements

The most important function of the alloying elements in heat-treatable steel is to increase hardenability. Increased hardenability makes possible the hardening of larger sections and the use of an oil rather than a water quench to minimize distortion and to avoid quench cracking.

When the standard alloy steels are considered, it is found that, for practical purposes, all compositions develop the same tensile properties when quenched to martensite and tempered to the same hardness below 50 HRC. However, it should not be inferred that all tempered martensites of the same hardness are alike in all respects. For example, plain carbon martensites have lower reduction-in-area values than alloy martensites. A further difference, sometimes important, is that fully quenched alloy steels require, for the same hardness levels, higher tempering temperatures than carbon steels. This difference in tempering temperature may serve to reduce the residual stress level in finished parts. The stress reduction could be an advantage or a disadvantage, depending on whether a controlled compressive stress is desired in the part. Although tensile properties may not differ significantly from one alloy steel to another, considerable differences may exist in fracture toughness and low-temperature impact properties. In general, steels with a higher nickel content, such as 4320, 3310, and 4340, offer much greater toughness at a given hardness level. In some applications, the toughness factor rather than hardenability may dictate steel selection, but hardenability is still important, because steels that can be fully quenched to 100% martensite are much tougher than those that cannot.

Usually, the least expensive means of increasing hardenability at a given carbon content is by increasing the manganese content. Chromium and molybdenum, already referred to as increasing hardenability, are also among the most economical elements per unit of increased hardenability. Nickel is the most expensive per unit, but is warranted when toughness is a primary consideration.

Important synergistic effects, not yet fully defined, can also occur when combinations of alloying elements are used in place of single elements. Some examples of known synergistic combinations are nickel plus manganese, molybdenum plus nickel, and silicon plus manganese.

Boron. Another potent and economical alloying element is boron, which markedly increases hardenability when added to a fully deoxidized steel. The effects of boron on hardenability are unique in several respects:

- A very small amount of boron (about 0.001%) has a powerful effect on hardenability
- The effect of boron on hardenability is much less in high-carbon than in low-carbon steels
- Nitrogen and deoxidizers influence the effectiveness of boron
- High-temperature treatment reduces the hardenability effect of boron

Recommended austenitizing temperatures for boron H-steels are given with the H-bands.

Figure 10 illustrates the very small amount of boron required for an optimum hardenability effect when appropriate protection of the boron is afforded by additions of titanium or zirconium. In carburizing steels, the effect of boron on case hardenability may be completely lost if nitrogen is abundant in the carburizing atmosphere. The cost of boron is usually much less than that of other alloying elements having approximately the same hardenability effect.

Fig. 10 Influence of effective boron content (β_{eff}) on the hardenability of an 8620 type steel. $\beta_{\text{eff}} = B - [(N - 0.002) - Ti/5 - Zr/15] \geq 0$. Source: Ref 5

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Effect of Grain Size

The hardenability of a carbon steel may increase as much as 50% with an increase in austenite grain size from ASTM 8 (6 to 10) to ASTM 3 (1 to 4). The effect becomes more pronounced if the carbon content is increased at the same time. When the danger of quench cracking is remote (no abrupt changes in section thickness) and engineering considerations permit, it may sometimes appear to be more practical to use a coarser-grain steel rather than a fine-grain or more expensive alloy steel to obtain hardenability. However, this is not recommended, because the use of coarser-grain steels usually involves a serious sacrifice in notch toughness and may lead to other difficulties.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Variations Within Heats

Segregation of carbon, manganese, and other elements always occurs during ingot pouring and solidification. As a result, the hardenability of the steel in these segregated portions will differ from that in the remainder of the ingot. In general, specimens taken from the top of the ingot have higher hardenability than steel from the middle, and specimens from the bottom of the ingot will have lower hardenability than steel from the middle. This gradual increase in hardenability from the bottom of the first ingot to the top of the last ingot is illustrated in Fig. 11(a) for 16 heats of 1035 carbon steel. The hardenability spread for 8 heats of 1035 steel containing 0.05 to 0.12% Mo, plotted in Fig. 11(b), shows a similar trend. Comparison between Fig. 11(a) and 11(b) shows the effect of molybdenum on hardenability.

Fig. 11 Effect of test location of (a) 1035 steel and (b) 1035 steel with 0.05 to 0.12% Mo on SAC (Rockwell-in.) hardenability

The same effect is observed in alloy steels. End-quench hardenability test results for one heat of 4028 steel (Fig. 12) show higher hardenability for a cast bar taken from the top of the last ingot of the heat than for a specimen from the melting floor and labeled cast end-quench specimen. The latter was taken from about the middle of the heat. After the heat of steel

was rolled, the hardenability was slightly lower, as shown by the curve representing results on eight end-quench specimens. Data for 465 heats of ten other steels are summarized in Fig. 13.

Fig. 12 Variation of hardenability within a heat of 4028 steel

Fig. 13 Variation in hardenability from first to last ingot in heat for several carbon and alloy steels

Effect of Hot Working. Processing variables, such as the amount of hot working and the location of the test specimen in the semifinished section, have an effect on hardenability. A 330 mm (13 in.) square bloom of 1330 steel was forged progressively to bar sizes of 305, 255, 205, and 150 mm (12, 10, 8, and 6 in.) in diameter. Each bar size was evaluated by tests on end-quench specimens cut from five locations (center, quarter-radius, half-radius, three-quarter-radius, and just below the surface). Data in Fig. 14 show that the variation in hardenability narrows as the bar size is decreased by hot work.

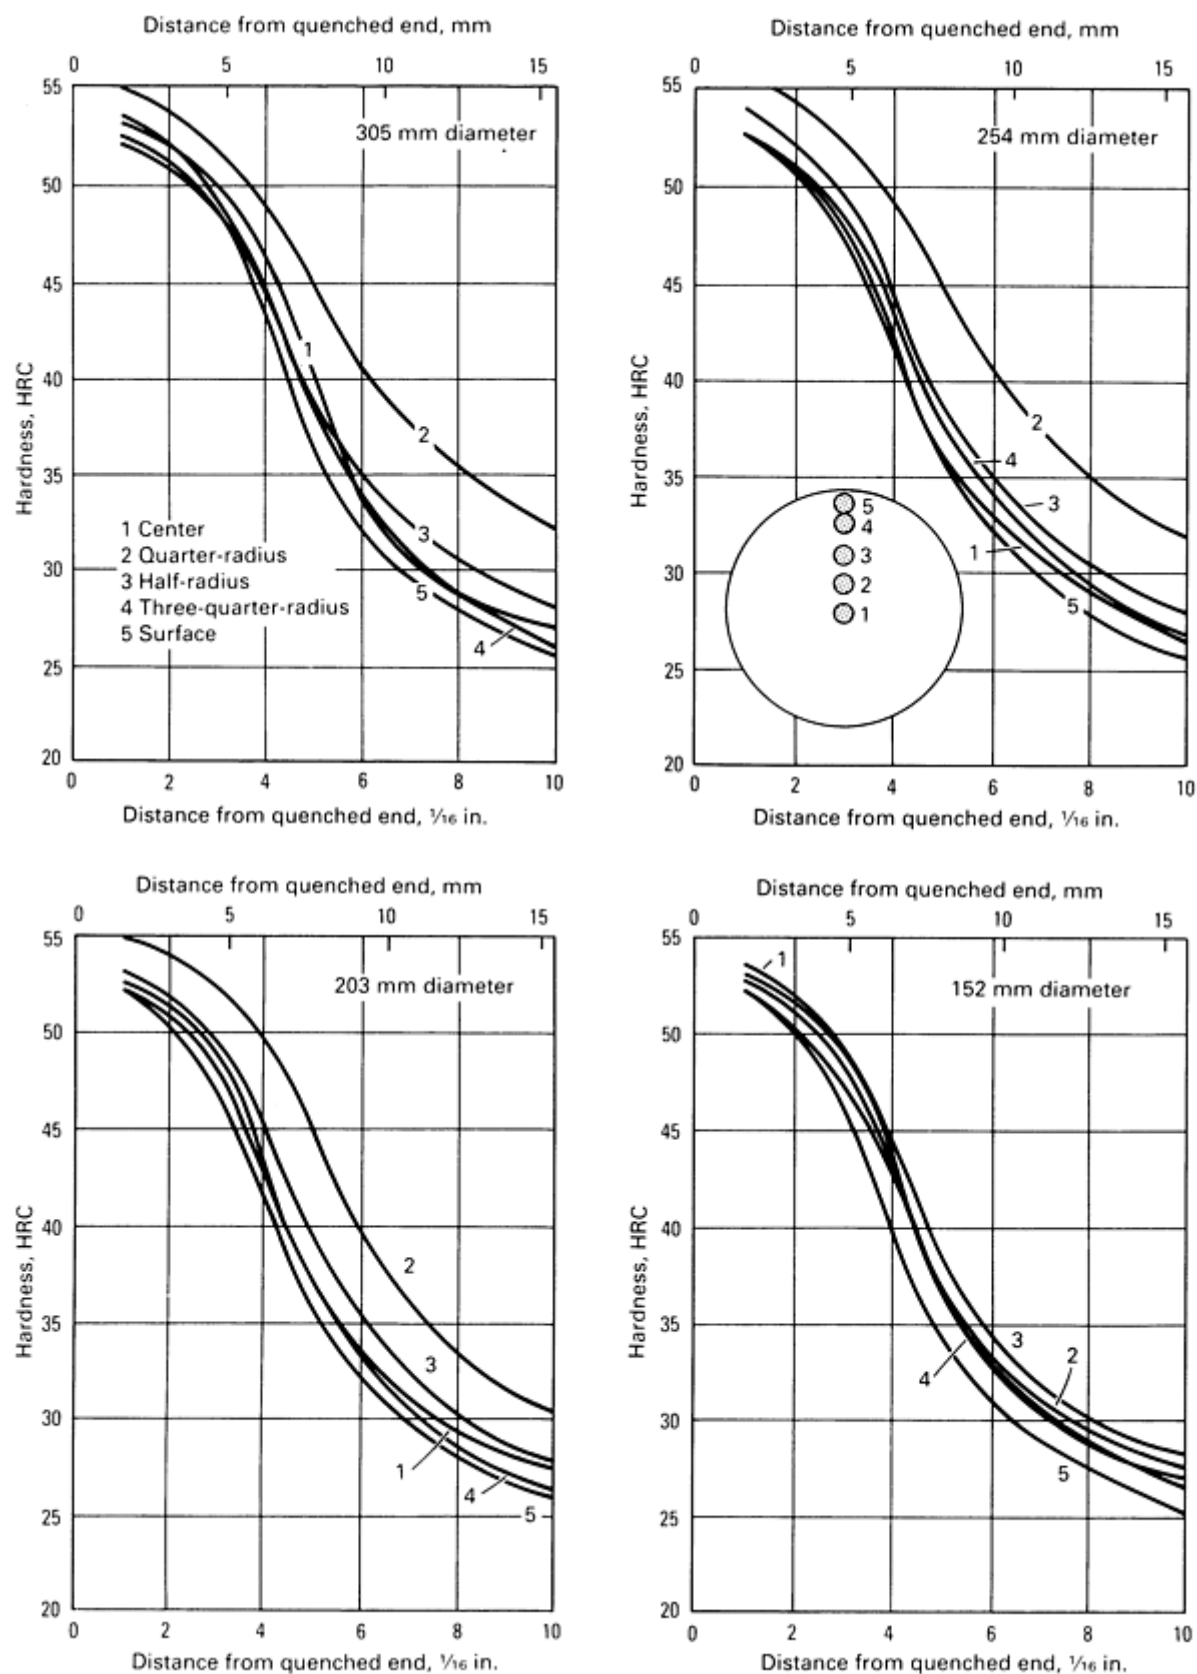

Fig. 14 Effect of hot working and location of test bars on end-quench hardenability of 1330 steel. A 330 mm (13 in.) bloom was progressively forged to bars of the diameters shown.

Determining Hardenability Requirements

The basic information needed to specify a steel with adequate hardenability includes:

- The as-quenched hardness required prior to tempering to final hardness that will produce the best stress-resisting microstructure
- The depth below the surface to which this hardness must extend
- The quenching medium that should be used in hardening

As-Quenched Hardness. The Iron and Steel Technical Committee of the Society of Automotive Engineers (SAE) War Engineering Board approved and issued the relation shown in Fig. 15(a) as a recommendation for as-quenched hardness as a function of the hardness desired after tempering. Figure 15(a) does not specify the degree of hardening (percentage martensite) preferred in obtaining the as-quenched hardnesses indicated. It is possible, as shown in Fig. 15(b), to select steels that will produce these hardnesses with less than 90% martensite.

Fig. 15 Curves for steel selection based on hardness. (a) Minimum as-quenched hardness to produce various final hardnesses after tempering. (b) Dependence of as-quenched hardness on percentages of martensite and carbon

To ensure optimum properties, common practice is to select the steel with the lowest carbon content that will produce the indicated as-quenched hardness using the quenching medium available (or one that can be made available). Following this procedure, the structures possessing the indicated hardnesses would be fully hardened; that is, they would contain more than 90% martensite, which is a common and practical definition of full hardening and the one employed by the SAE committee. For components subjected to bending in service, it is considered adequate to have 90% martensite at the three-quarter-radius location. To ensure this, hardness levels are specified at half-radius.

Depth of Hardening. The depth and percentage of martensite to which parts are hardened may affect their serviceability, but it always affects the hardenability required and therefore the cost. In parts less highly stressed in bending, hardening to 80% martensite at three-quarter-radius of the part as finished may be sufficient; in other parts, even less depth may be required. The latter include principally those parts designed for low deflection under load, in which even the exterior regions are only moderately stressed. In contrast, some parts loaded principally in tension and others operating at high hardness levels, such as springs of all types, are usually hardened more nearly through the section. In automobile leaf springs, the leaves are designed with a low section modulus in the direction of loading. The allowable deflection is large, and most of the cross section is highly stressed.

In general, hardening need be no deeper than is required to provide the strength to sustain the load at a given depth below the surface. Therefore, parts designed to resist only surface wear, pure bending, or rolling contact often do not justify the cost of providing the hardenability required for hardening through the entire cross section.

When service requirements mandate that hardening must produce more than 80% martensite, the section size that can be hardened to a prescribed depth decreases rapidly as the percentage of martensite required increases. For example, let us assume that 95% martensite (51 HRC minimum hardness) is required in 8640H steel. Then the largest section size that can be hardened to the center in oil would be 16 mm ($\frac{5}{8}$ in.); a 25 mm (1 in.) section could be hardened to only three-quarter-radius. Again, on the basis of 95% martensite, the deepest hardening of standard steels, 4340H, will harden to the center of a 51 mm (2 in.) section; on the basis of 80% martensite (45 HRC), a 92 mm ($3\frac{5}{8}$ in.) round will harden to the center in oil.

The above examples emphasize the need for engineering judgment in requiring very deep hardening or unusually high percentages of martensite. When these requirements are not wholly justified, the results are overspecification of steel at higher cost and greater likelihood of distortion and quench cracking.

Quenching Media. The cooling potential of quenching media is a critical factor in heat-treating processes because of its contribution to attaining the minimum hardenability requirement of the part or section being heat treated. The cooling potential, a measure of quenching severity, can be varied over a rather wide range by:

- Selection of a particular quenching medium
- Control of agitation
- Additives that improve the cooling capability of the quenchant

Any or all of these variables can be employed to increase quenching severity and provide the following advantages:

- Permit the use of less expensive (lower-alloy) steels of lower hardenability
- Optimize the properties of the steel selected
- Permit the use of less expensive quenching media
- Improve productivity and achieve cost reductions as a result of shorter cycle times and higher production rates

In practice, however, two other considerations modify the selection of quenching medium and quenching severity: the amount of distortion that can be tolerated and the susceptibility to quench cracking.

In general, the more severe the quenchant and the less symmetrical the part being quenched, the greater the size and shape changes that result from quenching and the greater the risk of quench cracking. Consequently, although water quenching is less costly than oil quenching and water-quenched steels are less expensive than those requiring oil quenching, it is important that the parts to be hardened be carefully reviewed to determine whether the amount of distortion and the possibility of cracking as a result of water quenching will permit taking advantage of the lower cost of water quenching. Oil, salt, and synthetic water-polymer quenchants are alternatives, but their use often requires steels of higher alloy content to satisfy hardenability requirements.

A rule regarding selection of a steel and quenching medium for a given part is that the steel should have a minimum hardenability not exceeding that required by the quenching severity of the medium selected. The steel should also contain the lowest carbon content compatible with the required hardness and strength properties. This rule is based on the fact that the quench cracking susceptibility of steels increases with a decrease in M_s temperature and/or an increase in carbon content.

Table 1 lists typical quenching severity, or H , values for the common quenching media and conditions. These data are for media containing no additives. Figure 16 shows the effects of additives and of other quenching media. According to these data, considerable improvement in the cooling capability of quenchants can be obtained by such additions as water to hot

salt, proprietary additives to oil, and polyalkylene glycol (polymer) to water. The polymer-water mixtures polyacrylamide gel (PAG), polyvinyl pyrrolidone (PVP), and polyvinyl alcohol (PVA) are gaining favor because they can be made to span the quenching severity range from oil to water by simple variation of the glycol (polymer) concentration in water. Also, because they are free of fire hazards and obnoxious environmental pollution agents, they have no adverse effect on working conditions. The quenching severity of these media should be tested at frequent intervals because dragout and thermal breakdown may affect their quenching efficiency.

Table 1 Quenching severities, H, for various media and quenching conditions

Quenchant agitation	Typical flow rates		Typical H values			
	m/min	sfm	Air	Mineral oil	Water	Brine
None	0	0	0.02	0.20-0.30	0.9-1.0	2.0
Mild	15	50	...	0.20-0.35	1.0-1.1	2.1
Moderate	30	100	...	0.35-0.40	1.2-1.3	...
Good	61	200	0.05	0.40-0.60	1.4-2.0	...

Fig. 16 Approximate quench severities for quenching media containing additives to improve cooling capacity

Hardenability Versus Size and Shape. When end-quench data such as those shown in Fig. 2 are available, either of two methods can be used to estimate the hardenability a steel part of given size and configuration must have to achieve the desired hardness, strength, and microstructure at critical locations when quenched in various production media. These methods are:

- *Method 1:* The correlation of end-quench hardness data (J_{eh}) with equivalent hardness locations in variously quenched shapes
- *Method 2:* The correlation of end-quench cooling rate data (J_{ec}) with equivalent cooling rate locations in variously quenched production shapes.

Method 1 (Fig. 17) is the more accurate and preferred method, because in practice it has been found that, when cooling at the same rates, large sections produce somewhat lower hardnesses than smaller sections, including end-quench and air hardenability bars. This difference has been attributed to two factors (Ref 6):

- Higher contraction stresses in large parts accentuate the transformation of austenite
- Quenching severity, H , decreases with an increase in section size

Also, in using the cooling rate method (method 2), it is difficult to determine cooling rates with a high degree of accuracy. Nevertheless, correlations that equate cooling conditions along the end-quench bar (J_{ec}) with those in production shapes quenched in various liquid media are also extremely useful when attempting to establish the required hardenability and/or quenching conditions for a production part.

Jominy equivalent hardness (J_{eh}) rates are determined by comparing the hardnesses of cross sections of parts receiving the established production heat treatment to hardnesses obtained on end-quenched bars of the same steel. A typical procedure is as follows:

1. Select hardening and quenching conditions that the production hardening equipment can easily fulfill.
2. Select a low-hardenability steel, such as 8620, 4023, or 1040, and manufacture a quantity of finished components: gears, bearings, shafts.
3. Quench a number of these components (in the uncarburized condition) in the production facility.
4. Measure the hardnesses obtained at all critical locations from the surface to the core.
5. Compare the measured hardness values at these locations with equivalent hardness values produced at some end-quench (J_{eh}) location on a Jominy bar made from the same heat and end quenched from the same thermal conditions.
6. The J_{eh} values obtained in this fashion define the equal hardness cooling conditions for each location in the production-

quenched component.

7. Finally, select from available end-quench data a steel that will produce the hardnesses required at each critical J_{eh} location in the finished production part. If end-quench data are not available, calculate a suitable composition by one of the standard methods.

Fig. 17 Determination of Jominy equivalent hardness (J_{eh}) rates

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

General Hardenability Selection Charts

Figures 18 and 19 show correlations of J_{ec} equivalent cooling rates in end-quench hardenability specimens and round bars of up to 102 mm (4 in.) in diameter when quenched in oil, water, brine, and hot salt at various controlled agitation rates. They correlate bar diameter with equivalent positions on the end-quench hardenability specimen for ten modes of quenching, for both scaled and scale-free bars, and with data grouped according to bar location instead of by quenching mode.

Brine (1), violent agitation	Water (2), 60 m/min (200 sfm)	Still water (3)	Oil (4), 230 m/min (750 sfm)	Oil (5), 60 m/min (200 sfm)	Oil (6), 15 m/min (50 sfm)	Still oil (7)
4.0	1.5	1.0	0.8	0.5	0.35	0.20

Fig. 18 Correlation of J_{ec} equivalent cooling rates in the end-quench hardenability specimen and round bars quenched in oil, water, and brine, (a), (c), and (e) Nonscaling austenitizing atmosphere. (b), (d), and (f) Austenitized in air

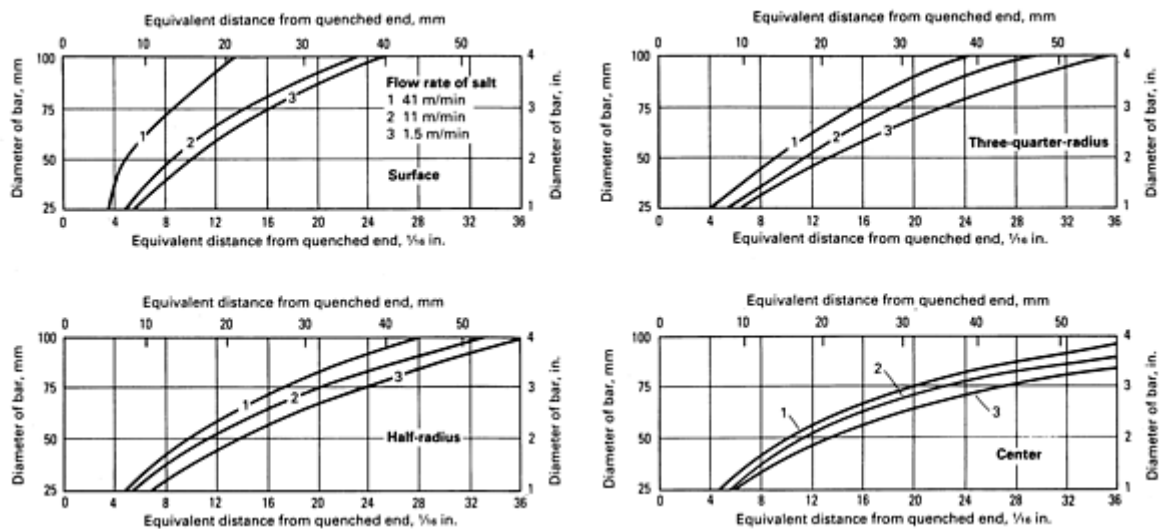

Fig. 19 Correlation of J_{ec} equivalent cooling rates in the end-quenched hardenability specimen and round bars quenched in salt at 205 °C (400 °F)

Table 2 has been devised to work with the charts in Fig. 18 and 19 and includes most of the steels for which H-bands have been established, showing the location on the end-quenched specimen of the low limit of the H-band for six different hardness levels that might be specified for as-quenched hardness; 55, 50, 45, 40, 35, and 30 HRC. The last two levels apply primarily to the core hardness of carburized parts.

Table 2 Classification of H steels according to minimum hardness at various distances from quenched end

Distance from quenched end, $\frac{1}{16}$ th in.	H steels with a minimum hardenability curve that intersects the specified hardness at the indicated distance from the quenched end of the hardenability specimen	Typical values ^(a) obtained by the use of Fig. 18 bar diameter (in.) for equivalent cooling rate at:					
		Three-quarter-radius		Half-radius		Center	
		Oil at 200 sfm; H = 0.5	Water at 200 sfm; H = 1.5	Oil at 200 sfm; H = 0.5	Water at 200 sfm; H = 1.5	Oil at 200 sfm; H = 0.5	Water at 200 sfm; H = 1.5

(a) If based on equivalent hardness, actual bar diameter will be less.

(b) High residual alloy

The use of Fig. 18 and Table 2 is described in the following example. This method substantially reduces the amount of chart hopping that has in the past been needed to examine all the available steels for the purpose of selecting one.

Example 1: Selection of a Steel with 38 mm ($1\frac{1}{2}$ in.) Diam Section Equivalent Having 45 HRC at Half-Radius.

This example traces the steps needed to select a steel that will harden to 45 HRC at half-radius in a part having a significant section equivalent to a 38 mm ($1\frac{1}{2}$ in.) diam bar. First, it is assumed that, to prevent distortion, the quench will be in oil at 60 m/min (200 sfm) ($H = 0.5$) and that a nonscaling atmosphere will be used for heating to the austenitizing temperature. Therefore, the chart for half-radius in Fig. 18(c) is applicable.

The following steps will then lead to the selection of a steel. First, trace horizontally at the level of $1\frac{1}{2}$ in. diameter to the curve for oil quench at 60 m/min (200 sfm) (curve 5). From the point of intersection with this curve, trace vertically to the x -axis to determine the location on the end-quenched bar that has the same cooling rate as the point at half-radius in the $1\frac{1}{2}$ in. round. This location is $\frac{6.5}{16}$ from the quenched end of the bar. Then turn to the section of Table 2 that gives the location of 45 HRC on the end-quenched bar for the various H-steels. Here it is found that four steels will produce 45 HRC at $\frac{6.5}{16}$ from the end of the bar: 8640, 8740, 5150, and 94B30. If some additional hardenability is not undesirable, steels that will produce 45 HRC at $\frac{7}{16}$ can be included--4137, 8642, 6145, and 50B40. Steel 9261 is also in the same category, but it would not be applicable, because it is a spring steel used only when the asquenched hardness must be as high as 50 to 55 HRC. Therefore, eight steels are available that will meet the hardenability requirements of the stipulated specification. From knowledge of other characteristics of these steels, including machinability, forgeability, crackability, distortion, availability, and cost, the selector can decide which of these eight will be the most desirable for the part in question.

Scaled Rounds. When values for scaled round bars are desired, Fig. 18(b), 18(d), and 18(f) can be used. However, prediction of results for sizes less than 25 mm (1 in.) in diameter should not be the basis for important decisions involving costly purchases without further checking, because values for these sizes were obtained by extrapolation.

Figure 20 shows another correlation for rounds based on the equivalent hardness criterion. In Fig. 20, cooling conditions from the surface to the center of rounds of various sizes quenched in media ranging in quenching severity from 0.20 to infinity are correlated with J_{eh} ; they are given in $\frac{1}{16}$ in. units producing the same hardness on the end-quench bar. Figure 20 is especially useful for estimating through-section strength, because the entire hardness profile of the prospective steel (and, to a degree, microstructure as well) can be predicted for rounds with different diameters from one set of end-quench data. Instructions for the procedure are given in the caption.

Fig. 20 Correlation of J_{eh} equivalent hardness positions in end-quenched hardenability specimen and various locations in round bars quenched in oil, water, and brine. The dashed line shows the various positions in $\frac{1}{2}$ to 4 in. diam rounds that are equivalent to the $\frac{8}{16}$ in. distance on the end-quench bar. To determine cross-sectional hardnesses from results of end-quench tests, pick out the end-quench hardness at an appropriate point on the bottom line and extend an imaginary line upward to the curved line that corresponds to the quenching severity needed to obtain that hardness for the given diameter of round.

Rectangular or Hexagonal Bars and Plate. Except in critical or borderline applications, size relationships for rounds can be applied without correction to square or hexagonal sections. Figures 18, 19, and 20 can also be used for rectangular bars in which the ratio of width to thickness (W/T) is less than 4, but the value 1.4 times the thickness should be used as the equivalent round. Large plates cool considerably more slowly than bars. The cooling rate relationships shown in Fig. 21 and 22 apply to these shapes.

Fig. 21 Correlation of equivalent cooling rates in the end-quench specimen and quenched plates

Fig. 22 Correlation between J_{ec} and center cooling rates in plates quenched at various severities

Tubular Parts. The application of end-quenched hardenability data to the selection of steel for hollow cylindrical sections is based largely on production experience with similar parts. There has been some progress in equating tubular sections to round bars and in developing dimensionless temperature-time charts for long hollow cylinders. Hollomon and Zener (Ref 7) determined by calculation the diameter of solid steel cylinders that, when quenched in a given medium, could be expected to have the same hardness at the center as the minimum hardness in the wall of hollow cylinders when quenched in the same medium. The rule of thumb of doubling the tube wall thickness to obtain the diameter of an equivalent solid bar is a useful first approximation.

Estimating Hardenability. When actual end-quenched hardenability data are unavailable, the hardening performance of a steel of given chemical composition can be estimated from calculated hardenability data. The various methods proposed for calculating hardenability are given in the section "Calculation of Hardenability" in this article. Details can be found in Ref 3 and 8, 9, 10, 11, 12, 13.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Use of the Charts

The true measure of applicability of any steel to a part requiring heat treatment is the relation of its hardenability to the critical cross section of the part at the time it is heat treated. The term critical cross section refers to that section of the part where service stresses are highest and therefore where the highest mechanical properties are required. For example, if the part is a rough forging 64 mm ($2\frac{1}{2}$ in.) in diameter at the critical cross section, which is later machined to 50 mm (2 in.) in diameter, and the finished part must be hardened to three-quarter-radius (that is, 6.4 mm, or $\frac{1}{4}$ in., deep), then the hardenability of the steel must be such that the rough forging will harden 13 mm ($\frac{1}{2}$ in.) deep.

Figure 23 shows the correlation between cooling rates along the end-quench hardenability specimen and at four locations in round bars up to 102 mm (4 in.) in diameter for both oil and water quenching at 60 m/min (200 sfm). The curves in Fig. 23 provide data that can be used directly in steel selection. Following is an example of their practical application to a specific problem of steel selection.

(a)

(b)

Fig. 23 Equivalent cooling rates for round bars quenched in water (a) and oil (b). Correlation of equivalent cooling rates in the end-quenched hardenability specimen and quenched round bars free from scale. Data for surface hardness are for mild agitation; other data are for 60 m/min (200 sfm).

Example 2: Use of Hardenability Charts to Verify that 4140H Steel Will Fulfill Hardness Specifications for a 44.45 mm (1.75 in.) Diam Shaft.

A shaft 44.45 mm (1.75 in.) in diameter and 1.1 m ($3\frac{1}{2}$ ft) long is required in a machine. The engineering analysis indicates that the torsion requirements will approach a maximum of 170 MPa (25 ksi) and that the bending stresses will reach a maximum of 550 MPa (80 ksi). Because several other parts in production in the same plant are being made from 4140H steel, it is desired to know whether 4140H has enough hardenability for this shaft.

Because the shear stress in torsion is about one-half that in bending, the latter will be the primary consideration. In bending, stresses approach zero in the neutral axis; therefore, the steel need not be hardened completely to the center. This is helpful because the distribution of stress in quenching will decrease the danger of quench cracking and, after tempering, should leave the exterior portion of the shaft in compression.

In order to withstand a fatigue load of 550 MPa (80 ksi) in bending, a minimum hardness of 35 HRC is required. For this example, it will be assumed that 35 HRC should be obtained by tempering a structure that, as-quenched, contains at least 80% martensite. From experience with similar parts, it is known that the 80% martensite structure should be present down to the three-quarter-radius position in the shaft.

Because 4140H has a minimum carbon content of 0.37%, the first operation on the charts (Fig. 24) is to find the as-quenched hardness that corresponds to 0.37% C in an 80% martensite structure. As shown in the top chart of Fig. 24--the same data as in Fig. 1(d)--this as-quenched hardness is 45 HRC.

Result

80% martensite structure of 0.37% C has as-quenched hardness of 45 HRC

Required

45 HRC min at $\frac{3}{4}$ radius in a 44.45 mm (1.75 in.) diam shaft, oil quenched

To determine whether 4140H will meet requirement, start with 44.45 mm (1.75 in.) diameter

49 HRC

Minimum hardenability of 4140H meets the requirement

Fig. 24 Illustration of the use of hardenability data in steel selection

The original question (whether 4140H is appropriate for this part) can now be rephrased to read: Will 4140H provide the required minimum as-quenched hardness of 45 HRC at three-quarter-radius in the 44.45 mm (1.75 in.) diam shaft? To determine the answer to this question, enter the middle chart of Fig. 24 (this is the same as Fig. 23b) at the diameter level of 44.45 mm (1.75 in.) and move horizontally to an intersection with the $\frac{3}{4}$ -radius curve. This intersection occurs at the $\frac{6.5}{16}$ position on the specimen. Then, move down vertically into the bottom chart to an intersection with the curve for minimum hardenability of 4140H. The intersection occurs at 49 HRC. Because no more than 45 HRC is required, 4140H has more than enough hardenability for this part.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

H-Steels

Hardenability bands are Jominy curves, based on much historical data, that describe the expected hardenability of many grades of carbon and alloy steels. The H-steels are guaranteed by the supplier to meet these limits for specific ranges of chemical composition. In general, the allowable composition ranges of H-steels are slightly wider than those of steels melted to composition specifications in order to accommodate differences in the residual levels and practices of different mills. These steels are designated by the letter "H" following the composition code or preceding the UNS designation.

The charts in the following article, "Hardenability Curves," in this Volume show composition limits and hardenability bands for SAE-AISI steels that can be purchased on a hardenability basis. The minimums of these bands are summarized in Table 2.

Current steelmaking technologies--ladle refining, for example--have permitted excellent control of composition. As a result, hardenability specifications much closer than those indicated by the H-bands can often be worked out between purchaser and supplier. The availability of fractional band hardenability is a function of both the base steel composition and the commonality of the grade.

When a H-steel is specified, the steel producer shows on the shipping papers or by some other acceptable means the hardenability characteristics of the heat involved. The heat hardenability is shown either by hardness values at specified reference points or at the following distances from the quenched end of the test specimen: $\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1, $1\frac{1}{4}$, $1\frac{1}{2}$, $1\frac{3}{4}$, and 2 in. No reading below 20 HRC is reported. The heat hardenability is determined from either a cast or a forged end-quench test bar.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Use of Hardenability Limits

H-band limits are shown graphically in the article "Hardenability Curves" in this Volume for convenience in estimating the hardness values obtainable at various locations on the end-quench test bar and for quick comparison of the various H-grades. However, the graphs are not used for specification purposes. Tables appearing with the graphs in the article "Hardenability Curves" in this Volume show the minimum and maximum Rockwell C hardness values at the corresponding distances from the quenched end of the standard end-quenched test specimen for all H-steels.

When desirable, the maximum and minimum limits at the $\frac{1}{16}$ -in. position can be specified in addition to the other two points. When it is necessary to specify more than two points on the hardenability band (exclusive of the maximum and minimum limits at $\frac{1}{16}$ in.), a tolerance of two points Rockwell C over a $\frac{3}{16}$ in. portion of either curve (except at $\frac{1}{16}$ in.) is permitted.

Maximum Hardenability Limits

As pointed out in the preceding paragraphs, maximum hardenability can sometimes be specified as well as minimum. Although minimum hardenability is significant in relation to the maximum section to be hardened, the maximum hardenability is related chiefly to minimum sections and their tendencies to distort or crack, especially when made from higher-carbon steels.

For example, assume that there is a part for which 4137 will not quite provide the necessary minimum hardenability. By changing to 4142, the minimum hardenability will be increased by $\frac{4}{16}$ at 45 HRC, a worthwhile increase. The danger is that, by increasing carbon to provide greater hardenability, the maximum as-quenched hardness is also increased. Many parts have a thin section sensitive to both maximum hardenability and high as-quenched hardness, and because of this combined effect of higher carbon, such sections often break during quenching.

The higher-carbon steels transform to martensite at a lower temperature; that is, the M_s temperature is lower. At this temperature, the steel is less plastic and therefore less able to withstand the strains set up by the volume increase (about $1\frac{1}{2}\%$) when austenite transforms to martensite. Also, the higher-carbon martensites are harder and more brittle and cannot withstand the severe strains set up in quenching as well; therefore, pieces with an unfavorable configuration, such as a shaft with a flange, may develop quench cracks.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Steels for Case Hardening

Many alloy steels for case hardening are now specified on the basis of core hardenability. Although the same considerations generally apply as for the selection of uncarburized grades, there are some peculiarities in carburizing applications.

First, in a case-hardened steel, the hardenability of both case and core must be considered. Because of the difference in carbon content, case and core have quite different hardenabilities, and this difference is much greater for some steels than for others. Moreover, the two regions have different functions to perform in service. Until the introduction of lean alloy steels such as the 86xx series, with and without boron, there was little need to be concerned about case hardenability, because the alloy content combined with the high carbon content always provided adequate hardenability. This is still generally true when the steels are direct quenched from carburizing, so that the carbon and alloying elements are in solution in the case austenite. In parts that are reheated for hardening and in heavy-sectioned parts, however, both case and core hardenability requirements should be carefully evaluated.

The hardenability of the steels as purchased will be the core hardenability. Because these low-carbon steels, as a class, are shallow hardening and because of the wide variation in the section sizes of case-hardened parts, the hardenability of the steel must be related to some critical section of the part, for example, the pitch line or the root of a gear tooth. This is best accomplished by making a part of a steel of known hardenability, heat treating it, and then, by means of equivalence of hardness, relating the hardenability in the critical section or sections to the proper positions on the end-quench hardenability specimens, both base carbon and carburized.

Finally, notice that the relationship between the thermal gradient and the carbon (hardenability) gradient during quenching of a carburized part can make a measurable difference in the case depth as measured by hardness. That is, an increase in base hardenability can produce a higher proportion of martensite for a given carbon level, yielding a deeper measured case depth. Therefore, a shallower carbon profile and shorter carburizing time could be used to attain the desired result in a properly chosen steel.

Core Hardness. A common mistake is to specify too narrow a range of core hardness. When the final quench is from a temperature high enough to allow the development of full core hardness, the hardness variation at any location will be that of the hardenability band of the steel at the corresponding position on the end-quenched hardenability specimen. One way to alter this state of affairs is to use higher-alloy steels. In the commonly used alloy steels having a maximum of 2%

total alloy content, the range for the core hardness of sections such as gear teeth is 12 to 15 points HRC. Higher-alloy steels exhibit a narrower range; for example, in 4815 the range is 10 points, while in 3310 it is 8 points. Such steels are justified only for severe service or special applications.

In standard steels purchased to chemical composition requirements rather than to hardenability, the range can be 20 points HRC or more; for example, 8620 may vary from 20 to 45 HRC at the $\frac{4}{16}$ in. position. This 25-point range emphasizes the advantage of purchasing to hardenability specifications to avoid the intolerable variation possible within the ranges for standard chemistry steels. Without resorting to the use of high-alloy steels, another way to control core hardness within narrow limits is to use a final quench from a lower temperature, so that full hardness will be developed in the case without the disadvantage of excessive core hardness.

Case-Hardened Steel Applications. In addition to the complexities already mentioned, there are highly variable conditions in heat treating and sometimes differences of opinion, even among qualified engineers. The subject can be simplified to some extent by dividing it into applications involving, first, gears and similar parts and, second, all others.

Gears are almost always oil quenched because distortion must be held to the lowest possible level. This means that alloy steels are usually selected--which particular alloy is much debated. The lower-alloy steels such as 4023, 5120, 4118, 8620, and 4620, with a carbon range between 0.15 and 0.25%, are widely used and generally satisfactory. The first choice usually would be made from the last two steels mentioned, either of which should be safe for all ordinary applications. The final choice, based on service experience or dynamometer testing, should be the least expensive steel that will do the job. To this list should be added 1524, which, although not classified commercially as an alloy steel, has sufficient manganese to make it oil hardening up to an end-quench correlation point of $\frac{3}{16}$.

For heavy-duty applications, higher-alloy grades such as 4320, 4817, and 9310 are justifiable if based on actual performance tests. The life testing of gears in the same mountings used in service, to prove both the design and the steel selection, is particularly important.

The carbonitriding process extends the use of carbon steels such as 1016, 1018, 1019, and 1022 into the field of light-duty gearing by permitting the use of oil quenching in teeth of eight diametral pitch and finer. Steels selected for such applications should be specified silicon-killed fine-grain in order to ensure uniform case hardness and dimensional control. The core of such gears will, of course, have the properties of low-carbon steel, oil quenched. In the thin sections of fine-pitch teeth, this may be up to 25 HRC. The carbonitriding process is usually limited, for economic reasons, to maximum case depths of approximately 0.6 mm (0.025 in.).

Nongear Applications. In other applications, when distortion is not a major factor, the carbon steels described above, water quenched, can be used up to a 50 mm (2 in.) diameter. In larger sizes, low-alloy steels, water quenched, such as 5120, 4023, and 6120, can be used, but possible distortion and quench cracking must be guarded against.

Hardenability of Carbon and Low-Alloy Steels

Revised by Harold Burrier, Jr., The Timken Company

Steel Castings

Cast steels have about the same hardenability values as their wrought counterparts of the same composition. Because of their coarser grain, steels in the as-cast condition frequently show higher hardenability than the same steels in the wrought condition, but after they are normalized, hardenability will be more nearly equal. Variation in the hardenability of cast steels is caused by the same factors as in wrought steels.

Results from tests on standard end-quench specimens taken from various locations within a heavy casting reveal no significant effect of location on the hardenability of a modified 4032 steel (Fig. 25). Additional data on the hardenability of cast steels are given in SAE J434 and J435 and in Ref 14.

Fig. 25 Range of results for hardenability specimens cut from various locations in a 4032 alloy modified 1.35% Mn steel casting. Dimensions in illustration given in inches

Hardenability Curves

Introduction

HARDENABILITY CURVES for more than 80 types of carbon and alloy H-band steels comprise this article (Ref 1, 2). The tabular data used to compile these curves are also included with each graph. Values from these tables are used for specification purpose, and SAE recommends choosing two points to designate the hardenability.

Hardenability Curves

The two points may be designated in any one of the ways listed below and illustrated in Fig. 1:

- The minimum and maximum hardness values at any desired distance. This method is illustrated as points A-A and is specified as J43 to J54 = $\frac{3}{16}$ in. Obviously, the distance selected would be that distance on the end-quench specimen that corresponds to the section used by the consumer
- The minimum and maximum distances at which any desired hardness value occurs. This method is illustrated as points B-B and would be specified as J39 = $\frac{4}{16}$ to $\frac{9}{16}$ in.
- Two maximum hardness values at two desired distances, illustrated as points C-C and specified as J50 =

$$\frac{5}{16} \text{ in. (max), } J34 = \frac{12}{16} \text{ in. (max)}$$

- Two minimum hardness values at two desired distances, illustrated as points D-D and specified as $J35 = \frac{5}{16} \text{ in. (min), } J21 = \frac{16}{16} \text{ in. (min)}$
- Any minimum hardness plus any maximum hardness, E-E, specified as $J37 \text{ max} = \frac{10}{16}, J32 \text{ min} = \frac{6}{16}$

It should be noted that each H-band hardenability limit curve is presented graphically and in tabular form, in both metric and English units.

Fig. 1 Typical hardenability curve shown with English units. See text for discussion of designated points.

Hardenability Curves

Introduction

STEEL SHEET is widely used for industrial and consumer products, partly because it is relatively strong, easily joined, and readily available at moderate cost. However, it is not these factors, but the formability of steel sheets that is primarily responsible for its wide use. The term formability is commonly used to describe the ability of a steel to maintain its structural integrity while being plastically deformed into various shapes. However, not all shapes require the same forming characteristics, and a steel that has excellent formability in one application may exhibit poor formability in another application. In practice, therefore, formability must be optimized by selecting a grade of steel that has the forming characteristics needed to make the required shape.

These forming characteristics are normally estimated from an analysis of the mechanical properties of steel, which are determined by uniaxial tensile tests. Although this type of test does not simulate any commercial forming operations, the test results have been universally used for many years to evaluate formability, and some understanding of them is essential to the understanding of sheet steel formability. Sheet metal forming methods are described in detail in *Forming and Forging*, Volume 14 of *ASM Handbook*.

Examples of formed parts that require different forming characteristics in the steel are shown in Fig. 1. Part A was formed by drawing; that is, all the metal that was required to form the part from a flat blank came from the flanges. This shape requires that the steel have a high plastic-strain ratio, or r value, which determines the resistance of steel sheet to thinning during forming operations. Part C was formed by stretching; the flange on the blank was clamped during forming, and all of the metal that was required to form the part came from reducing the thickness of the metal. This type of part requires good ductility in the steel. However, the r value should be low, because high r values can cause failures of stretched parts. Part B has failed in plane strain, which is a type of stretching. Parts that develop this strain condition, such as automotive panels, require good ductility.

Fig. 1 Parts that required different forming characteristics in the steel sheet

This article discusses the mechanical properties and formability of steel sheet, the use of circle grid analysis to identify the properties of complicated shapes, and various simulative forming tests. It covers the effects of steel composition, steelmaking practices, and metallic coatings, as well as the correlation between microstructure and formability. A guide to the selection of steel sheet is also included.

The mechanical properties of steel sheet that influence its forming characteristics, either directly or indirectly, can be measured by uniaxial tension testing, such as that described in ASTM E 8. The tensile test results of particular interest include the yield strength, ultimate tensile strength, total elongation, uniform elongation, yield point elongation, plastic-strain ratio, planar anisotropy, and the strain-hardening exponent. Uniaxial tensile tests may be made with specimens obtained from longitudinal, diagonal, transverse, or other orientations relative to the rolling direction. Typical mechanical properties for common grades of hot-rolled and cold-rolled steel sheets are given in Tables 1 and 2.

Table 1 Typical mechanical properties of hot-rolled steel sheet

Type or quality	Special feature	Yield strength		Tensile strength		Elongation in 50 mm (2 in.), %	Hardness, HRB	Strain-hardening exponent, n	Plastic-strain ratio, r_m
		MPa	ksi	MPa	ksi				
Commercial	Standard properties	262	38	359	52	30	55	0.15	0.9
Drawing (rimmed)	Improved properties	241	35	345	50	35	50	0.18	1.0
Drawing (special killed)	Nonaging	241	35	345	50	40	50	0.20	1.0

(a) HRC

Yield strength of steel sheet is indicative of both formability and strength after forming. Several types of yielding behavior are observed in steel sheet (see Fig. 2). When yield point elongation occurs, the lowest value observed during discontinuous yielding is reported as the yield strength. In the absence of an abrupt change in the load-extension curve, the stress at 0.2% offset or 0.5% extension under load is reported as the yield strength.

Fig. 2 Load-extension curves for steel sheet having the same yield strength, but different characteristic behavior. (a) Annealed soft-rimmed or aluminum-killed steel; yield strength is the lowest stress measured during yield point elongation. (b) Lightly temper-rolled rimmed steel; stress at the jog in the curve is reported as yield strength. (c) and (d) Temper-rolled low-carbon steel. May be rimmed, aluminum-killed, or interstitial-free steel with no detectable yield point. The yield strength is calculated from the load at 0.2% offset (c) or from the load at 0.5% extension (d). (e) Rimmed steel with a yield point elongation due to aging at room temperature for several months. The yield strength is the lowest stress measured during yield point elongation.

In forming plain carbon steel sheet, a yield strength of 240 MPa (35 ksi) or more increases the likelihood of excessive springback and breakage during forming. However, the use of material have a yield strength of less than 140 MPa (20 ksi) may result in parts with insufficient strength levels.

High-strength, formable sheet steels have been developed for applications for which increased strength or reduced weight, in addition to moderate formability, are required. The yield strengths of these steels generally range from 345 to 690 MPa (50 to 100 ksi).

Total Elongation. After fracture, the tensile specimen is pieced together, and the length between gage marks is measured. In this manner, elongation is calculated and reported as a percentage of the original gage length, which is usually 50 mm (2 in.). (A gage length of 200 mm, or 8 in., may be used for heavier-gage metals.) Specimens of sheet

metals used for tensile tests usually have short, parallel-sided, reduced sections, but slightly tapered reduced sections are sometimes used to control the location of necking and fracture. Values of elongation resulting from tests of different specimens of the same material may vary because of differences in gage length, sheet thickness, edge preparation and finish, test methods, or other factors.

Typical values of the amount of elongation in 50 mm (2 in.) are listed in Tables 1 and 2 for common formable grades of steel sheet. Generally, an elongation of 35 to 45% in 50 mm (2 in.) is normal for conventional low-carbon steels, with higher values indicating better formability.

Uniform Elongation. The total elongation of a sheet tensile specimen comprises two parts, uniform elongation and postuniform elongation. For a material that follows the power relationship for hardening ($\sigma = K\varepsilon^n$), the uniform elongation (measured in true strain) is equal to the strain-hardening exponent, n . The postuniform elongation depends on both the strain-hardening behavior and the strain rate sensitivity response of the metal to the applied stress. When a neck forms, the strains and strain rate within the neck are greater than in the outside regions, and increased strain hardening may offset the weakening due to the reduced cross-sectional thickness, causing a shift of deformation to regions outside the neck.

The engineering elongation to maximum load, e_u , is related to the strain-hardening exponent, n , by the equation:

$$n = \ln(1 + e_u) \quad (\text{Eq 1})$$

Typical values of e_u for low-carbon steels range from 20 to 30%. The e_u and associated n values indicate the work-hardening rate of sheet metals and, thus, the capability of the metal to deform in stretch, plain-strain, and bending deformation modes. Other factors, such as strain-rate sensitivity, can enhance or detract from the capability of a metal to be formed into a part. For example, the n values of low-carbon steel and 1100-O grade aluminum are about the same; however, both the total elongation and the forming limit of aluminum are considerably lower than those of low-carbon steel because aluminum has a negative value of m , the strain-rate sensitivity in response to the applied flow stress:

$$m = \frac{\ln(\dot{S}_1 / \dot{S}_2)}{\ln(\dot{\varepsilon}_1 / \dot{\varepsilon}_2)} \quad (\text{Eq 2})$$

where σ is the flow stress and ε is the strain rate.

For sheet metals that fail by local necking, uniform elongation may not give a true estimate of formability. Estimates based on total elongation are often considered more reliable.

Yield point elongation is the portion of total elongation that occurs during discontinuous yielding at the yield stress. It is accompanied by the formation of surface defects known as Lüders lines, or stretcher strains, which are considered imperfections in many applications of steel sheet because of their unsightly appearance. Yield point elongation during tensile testing indicates that Lüders lines are likely to occur during forming.

Yield point elongation requires the presence of interstitial residual alloying elements, particularly carbon or nitrogen; consequently, low-interstitial steels do not exhibit this effect. Yield point elongation can be suppressed by temper rolling the steel sheet at the mill. However, unless the nitrogen has been combined with another element (usually aluminum), the steel will age harden after a period that varies from a few hours to a year or more (depending on storage temperature and other factors). Aged steels can be used in most forming operations, provided they are roller leveled or flex immediately before fabrication, although these methods are less effective than temper rolling.

Plastic-strain ratio, r , describes the resistance of steel sheet to thinning during forming operations. This is the ratio of the true strain in the width direction, ε_w , to the true strain in the thickness direction, ε_t , of plastically strained sheet metal:

$$r = \frac{e_w}{e_t} \quad (\text{Eq 3})$$

The plastic-strain ratio is related to the crystallographic orientation of low-carbon steels. A standard method for determining r by using the tension test is given in ASTM E 517. The value will vary with test direction (relative to the coil rolling direction) in anisotropic metals. An average value, r_m , (sometimes designated \bar{r}), represents the normal plastic anisotropy of the steel sheet:

$$r_m = \frac{r_o + 2r_{45} + r_{90}}{4} \quad (\text{Eq 4})$$

Hot-rolled and normalized cold-rolled steels are generally isotropic (r_m of 1.0). Rimmed steels usually have an r_m of 1.2, but this value may be higher in special cases, as with some low-manganese low-sulfur products. Aluminum-killed steels will be more anisotropic, with r_m of 1.6. Higher values (up to 2.5) may be attained by controlling composition and processing. The upper limit for commercial steels is about 3.0, although values near 3.0 are seldom achieved. Interstitial-free steels tend to have the highest r_m at approximately 2.0. The r_m value predicts the ability of metals to deform in draw.

Planar anisotropy may be reported as:

$$\Delta r = \frac{r_o + r_{90} - 2r_{45}}{2} \quad (\text{Eq 5})$$

Planar anisotropy is a measure of the amount of high points, or ears, that will develop on the edges of deep-drawn cylindrical cups or similar parts. High points in the rolling and transverse directions are noted when Δr is positive (for low-carbon, drawing-quality, aluminum-killed steel sheet). For some high-strength low-alloy steels, Δr is negative, and earing occurs at 45° to the rolling direction. For most applications, values of Δr near 0 are preferred, because such values imply a minimal tendency to form ears when metals are drawn into cylindrical cups.

The strain-hardening exponent, n , is the slope of the true stress-true strain curve, when plotted on logarithmic coordinates. A significant portion of the curve is nearly a straight line for many low-carbon steels. The data are assumed to fit the equation:

$$\sigma = K\varepsilon^n \quad (\text{Eq 6})$$

The n value will normally be approximately 0.22 for low-carbon steels used to form complex-shape parts. Higher values (up to 0.26) indicate improved capabilities to deform in stretch. Freshly rolled rimmed steels generally have n values comparable to those of aluminum-killed steels. After aging, values of n for rimmed steels are less than those for aluminum-killed steels. Some low-carbon steels that are not fully processed for formability, especially hot-rolled grades, will have n values as low as 0.10, but most of the formable grades will have n values above 0.14.

The effects of different n values on strain distribution in critical regions of a specific formed part are shown in Fig. 3. Parts formed from steel sheet with a low n value (0.21) may undergo excessive thinning and fracture in critical regions. Identical parts formed from sheet with a higher n value (0.23) frequently will be strong enough in the critical areas to transfer strain to adjacent areas, thereby avoiding failure during forming.

Fig. 3 The major strain ϵ_1 in the critical region of a formed part is more uniformly distributed for the steel having the higher value of n . One of these two parts (which are identical except for the n value of the steel selected) was strained to the point of excessive thinning; the other, made from steel with the higher n value, showed no inclination to fracture. Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Circle Grid Analysis

Uniaxial tension tests determine the mechanical properties of steel sheet under closely controlled, frictionless conditions, which are different from the conditions that normally occur during sheet metal forming operations. However, experience has shown that test results often correlate with the ability of a steel to be successfully formed into parts. The relationship is not always a simple one. For example, the parts shown in Fig. 1 require the steel to exhibit different r and n values for successful processing. With practice, the mechanical properties that are required to form simple shapes like those shown can be estimated, but the properties required to form more complicated shapes can best be determined using circle grid analysis.

To use circle grid analysis, a pattern consisting of uniformly spaced, uniformly sized circles (usually 2.5 or 5.0 mm, or 1.0 or 0.2 in., in diameter) is etched onto a flat sheet of steel that is to be formed, and the steel is then processed into the desired shape. The circles change into ellipses with the deformation of the gridded steel blank. The ellipses are then measured to determine the maximum dimension (major strain) and the minimum dimension (minor strain). These strains are then plotted on a forming limit diagram (Fig. 4). The location and magnitude of the plotted points on the diagram indicate the severity of the forming operation. Their position on the right (stretch) side or left (draw) side of the diagram indicates the strain condition in the steel, where 0% minor strain indicates a plane-strain condition. Experience has shown that breakage associated with critical strains on the right, or stretch, side may be resolved by increasing the total elongation in the steel. Breakage associated with strains on the left, or draw, side may be eliminated by increasing the r -value of the steel. The magnitude of all of the strains can be reduced by changing the sheet metal forming conditions.

Fig. 4 A forming limit diagram (FLD). Strains in the critical zone and above it will result in excessive breakage. Strain conditions on the left side require high r values, while strain conditions on the center and right side require good ductility (a high percentage elongation in tensile tests).

The diagram in Fig. 4 is for 0.914 mm (0.036 in.) thick drawing-quality steel sheets. The critical area curves will be lower for thinner steels and higher for thicker steels. The curves can also be adjusted to accommodate commercial quality steels and other grades with lower n values than drawing-quality steels. The adjustments are made by moving the plane-strain intercept, or the point at which the lower curve crosses the 0% minor strain line, according to Fig. 5.

Fig. 5 Relationship between the plane-strain intercept on a forming limit diagram (FLD_0) and the strain-hardening exponent as a function of thickness. FLD_0 depends only on thickness for values n greater than 0.21. Source: Ref 2

The plotted points on a forming limit diagram show the magnitude of the strains that develop in steel sheets that are processed into a particular shape. Although the magnitude of the strains will be slightly different in steels with different r values, the plotted points generally show the strain conditions that will occur in any steel that has been used successfully to make a particular part. Therefore, in theory, the quality of the steel that is used to perform the analysis should not be important. In practice, it is advantageous to determine the mechanical properties of the steel when the circle grid analysis is made because excessive strains exhibited by formable steel are a clear indication that changes in processing will be required.

Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Simulative Forming Tests

Numerous tests have been developed to observe and compare the performance of steel sheets under actual forming conditions. The best known are the Olsen, Erichsen, and Swift cup tests, and the limiting dome height (LDH) test. The Olsen and Erichsen cup tests measure steel-stretching performance, the Swift cup test measures steel-drawing performance, and the LDH test measures the performance of a steel under plane-strain conditions.

The Olsen cup test measures the maximum penetration of a 22 mm (0.875 in.) diam hemispherical punch into a clamped, flat blank of steel. The punch depth at failure is the Olsen cup value. The Erichsen test is similar, but the punch diameter is 20 mm (0.790 in.). Experience has shown that a conscientious operator using a specific testing machine can use the Olsen or Erichsen cup test results to evaluate the ductility of the steel. However, the correlation between the test results and the steel performance in many sheet metal forming operations has not been good.

The Swift cup test determines the maximum diameter circular blank that can be successfully drawn into a flat-bottom cup. The die is usually 100 mm (4 in.) in diameter, although other dimensions are also used. The results are expressed as the limiting draw ratio (LDR):

$$LDR = \frac{\text{Maximum diameter blank}}{\text{Cup diameter}}$$

The LDR is a measure of the drawability of the steel, and the test results correlate well with the r value.

The LDH test measures the resistance of a steel to failure under plane-strain conditions. The test sample is a 180 mm (7 in.) long rectangle with an experimentally determined width (~135 mm, or 5.25 in.) that is clamped and stretched to failure over a 100 mm (4 in.) diam hemispherical punch. The sample width is the width that is found to produce the minimum height in the test; this minimum height is the LDH value for that material.

The LDH value has been shown to correlate well with the performance of steel sheets in stretch-type automotive body panels, which normally fail under plane-strain conditions. However, it does not correlate with steel performance on deep-drawn panels.

All simulative forming tests are affected by friction between the sheet metal and the tooling. This creates problems with sample and tooling preparation because the factors that affect friction in sheet metal forming are poorly understood. In practice, the samples and tooling are usually cleaned with a light mineral oil and wiped dry before testing. This treatment provides sufficient lubricity to prevent a "stick-slip" effect, while minimizing the effect of the lubrication.

Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Effects of Steel Composition on Formability

Low-carbon sheet steels are generally preferred forming. These steels typically contain less than 0.10% carbon and less than 1% total intentional and residual alloying elements. The amount of manganese, the principal alloying addition, normally ranges from 0.15 to 0.35%. Controlled amounts of silicon, niobium, titanium, or aluminum may be added either as deoxidizers or to develop certain properties. Residual elements, such as sulfur, chromium, nickel, molybdenum, copper, nitrogen, and phosphorus, are usually limited as much as possible. In steelmaking shops, these amounts are based

on the quality of sheet being produced. Alloy sheet steels (including high-strength low-alloy grades) however, contain specified amounts of one or more of these elements.

Carbon content is particularly significant in steels that are intended for complex forming applications. An increase in the carbon content of steel increases the strength of the steel and reduces its formability. These effects are caused by the formation of carbide particles in the ferrite matrix and by the resulting small grain size. The amount of carbon in steel sheet is generally limited to 0.10% or less to maximize the formability of the sheet.

Manganese enhances the hot-working characteristics of the steel and facilitates the development of the desired grain size. Some manganese is also necessary to neutralize the detrimental effects of sulfur, particularly for hot workability. Typical manganese contents for low-carbon steel sheet range from 0.15 to 0.35%; manganese contents up to 2.0% may be specified in high-strength low-alloy steels. When the sulfur content of the steel is very low, the manganese content also can be low, which allows the steel to be processed to develop high r values.

Phosphorus and sulfur are considered undesirable in steel sheet intended for forming, drawing, or bending because their presence increases the likelihood of cracking or splitting. Allowable levels of phosphorus and sulfur depend on the desired quality level. For example, commercial-quality cold-rolled sheet must contain less than 0.035% P and 0.040% S. For more applications, phosphorus may be added to the steel to increase the strength. Sulfur usually appears as manganese sulfide stringers in the microstructure. These stringers can promote splitting, particularly whenever an unrestrained edge is deformed.

Silicon content in low-carbon steel varies according to the deoxidation practice employed during production. In rimmed steels (so called because of the rimming action caused by outgassing during solidification from the molten state), the silicon content is generally less than 0.10%. When silicon rather than aluminum is used to kill the rimming action, the silicon content may be as high as 0.40%. Silicon may cause silicate inclusions, which increase the likelihood of cracking during bending. Silicon also increases the strength of the steel and thus decreases its formability.

Chromium, nickel, molybdenum, vanadium, and other alloying elements are present in low-carbon steel only as residual elements. With proper scrap selection and control of steelmaking operations, these elements are generally held to minimum amounts. Each of these elements increases the strength and decreases the formability of steel sheet. High-strength low-alloy steels may contain specified amounts of one or more of these elements.

Copper is generally considered an innocuous residual element in steel sheet. The strengthening effect of copper is almost negligible in typical residual amounts of less than 0.10%. However, copper is added to steel in amounts exceeding 0.20% to improve resistance to atmospheric corrosion.

Niobium strengthens high-strength low-alloy steel through the formation of niobium carbides and nitrides. It can also be used either alone or in combination with titanium to develop high r values in interstitial-free steels. These alloying elements remove the interstitial elements carbon and nitrogen from solid solution. Consequently, the steel shows no yield point elongation.

Titanium is a strong carbide and nitride former. It helps develop high r values and eliminates yield point elongation and the aging of cold-rolled annealed steel sheet. Titanium streaks may be a problem in some grades, especially in the form of surface defects in exposed applications.

Aluminum is added to steel to kill the rimming action and thus produce a very clean steel known as an aluminum-killed, or special-killed, steel. Aluminum combines with both the oxygen and nitrogen to stop the outgassing of the molten steel when it is added to the ladle or mold. Aluminum also aids the development of preferred grain orientations to attain high r values in cold-rolled and annealed steel sheet. Elongated grains of an approximate ASTM 7 size are found in most well-processed aluminum-killed steels. Because the aluminum combines with the nitrogen, the steel is not subject to strain aging.

Nitrogen can significantly strengthen low-carbon steel. It also causes strain aging of the steel. The effects of nitrogen can be controlled by deoxidizing the melt with aluminum.

Cerium and other rare earth elements may be added to steel to change the shape of manganese sulfide inclusions from being needlelike or ribbonlike to being globular. Globular inclusions reduce the likelihood of cracking if the sheet is formed without restraining the edges.

Oxygen content of molten steel determines its solidification characteristics in the ingot. Excessive amounts of oxygen impede nitride formation and thus negate the effects of alloying elements added to minimize strain aging. Deoxidizers such as silicon, aluminum, and titanium will control the oxygen content. When oxygen combines with these deoxidants, complex nonmetallics are formed. Although most nonmetallics dissolve in the slag, some may become trapped in the steel, causing the surface defects of seams and slivers.

Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Effects of Steelmaking Practices on Formability

The formability of steel sheet is determined to a great extent by the steelmaking practices employed in manufacturing. The user of steel sheet normally specifies certain characteristics for the sheet, thus ensuring that the material can be formed in a predictable manner. Adherence to these specifications also implies that the producer of the sheet has observed whatever steelmaking practices are necessary to enable the product to perform as indicated. The user can specify either hot-rolled or cold-rolled sheet, and he must select an appropriate quality designation. Sometimes deoxidation practice is specified. The user has some latitude in choosing the surface finish of the sheet. Of course, the user specifies the dimensions and tolerances of the sheet and the type of edge to be supplied.

Hot-rolled steel is rolled to its final thickness in an elevated-temperature process. The finishing temperature is determined by the composition of the steel and the desired properties. In the as-hot-rolled condition, the steel has a dark-gray oxide coating on its surface, which offers limited corrosion protection as long as it is undisturbed. However, the oxide flakes off during forming and may be undesirable around the press. Because the oxide coating also interferes with steel surface lubricants, it should be removed before the final finishing of most formed parts. Hot-rolled steel may be ordered pickled (using either hot sulfuric or hydrochloric acid to remove the oxide) and oiled to inhibit in-transit rusting. Hot-rolled steel in the as-pickled condition will show stretcher strains or Lüders lines on the surface after forming. Whenever surface appearance is important, the steel should be ordered with a temper-rolled surface (skin pass of less than 2% cold reduction) to reduce this tendency. If aging is a problem because of storage requirements, special-killed hot-rolled steel should be ordered.

There is no preferred grain orientation providing high r values in hot-rolled steel, but improved grain size and resistance to longitudinal splitting may be attained by closely controlling chemical composition, which differs between commercial- and drawing-quality hot-rolled steel. Higher strength levels (when necessary for the part being formed) are obtained by alloy additions and processing controls to develop improved structure. Because higher strength is associated with forming problems such as lower ductility, increased springback, and longitudinal bend failures, only high-strength low-alloy steels designed for improved formability should be used in structural parts made by press operations. Mechanical properties of several types of hot-rolled sheet are given in Table 1.

Cold-rolled steel sheet forming is produced by the cold reduction of hot-rolled pickled coils, followed by annealing and possibly additional processing, such as temper rolling. Class 1 (E, exposed) should be ordered when a controlled surface finish is required. Class 2 (U, unexposed) is intended for applications in which surface appearance is not of primary importance. Both classes are available as commercial-quality, drawing-quality, or drawing-quality special-killed cold-rolled steel. Mechanical properties of cold-rolled steel sheet are given in Table 2.

Most cold-rolled steels exhibit yield point elongation in the as-annealed condition. This appears as Lüders lines, or stretcher strains, on the surface of formed parts (for example, flat areas near the corners of pan-shape draws) that have been subjected to moderate forming operations. The yield point elongation may be removed by temper rolling the annealed coils. Because temper coiling strengthens the steel and reduces its ductility, it is usually limited to 0.5 to 1.5% elongation of the strip. Temper rolling under tension is more effective than flex rolling or roller leveling for eliminating yield point elongation because the steel is more uniformly strained through the thickness. These latter methods are sometimes used the plants of fabricators because the equipment is less expensive and because it permits the use of aged coils of rimmed steels that may show strain on the surface of formed parts.

In addition to many as-processed surface finishes, cold-rolled sheet may be ordered with a metallic coating that provides corrosion protection or a decorative finish that reduces the manufacturing costs of parts such as appliances or building panels.

Rimmed steels are available as both hot-rolled and cold-rolled products. The rimming action caused by outgassing during solidification produces a relatively pure iron layer on the surface of the ingot. Thus, rimmed steel generally has a better surface finish than killed steel. After the annealing treatments used to regain ductility in the product following cold reduction to final thickness, rimmed steels must be temper rolled to prevent the formation of Lüders lines during forming.

The two available quality levels of rimmed steel are achieved by controlling chemical composition and annealing practice. Commercial quality is standard, whereas drawing quality is produced under stricter tolerance levels for impurities and is given a longer anneal to ensure uniformity throughout the coil, as well as good formability. Rimmed steels are more suited to stretch-type deformation than to deep drawing, for which aluminum-killed steels are generally recommended. Rimmed steels will age after a period of time following temper rolling. Consequently, there is a time limit on any performance guarantee on drawing-quality rimmed steel.

Aluminum-killed steels are deoxidized with aluminum and, possibly, with silicon. As already mentioned, use of aluminum results in a very clean steel, known as aluminum-killed or drawing-quality special-killed steel. Exceptional resistance to thinning through the sheet thickness (as measured by the plastic strain ratio, r) can be developed through the controlled processing of these steels. Because the pure iron skin characteristic of rimmed steel does not exist in aluminum-killed steel, surface imperfections may occasionally be encountered on aluminum-killed sheet. Both class 1 and class 2 drawing-quality aluminum-killed steels are produced. It should be noted that some aluminum-killed steels that cannot meet the formability requirements for drawing-quality sheet are sold as commercial-quality steel.

Interstitial-free steel is vacuum degassed to reduce the amounts of the interstitial elements carbon, nitrogen, and oxygen. It is usually processed to achieve high values of r_m (~ 2.00). This type of steel is not subject to strain aging at any stage of processing or manufacture; it exhibits no yield point elongation. Interstitial-free steel can withstand deeper draws with less breakage than other grades of steel sheet, and coated products made from it generally retain excellent formability.

Surface finish may be specified for cold-rolled steel sheet. The need for uniformity among parts that must have matching surface finishes (such as automobile fenders and hoods), even when made from different materials, often dictates the sheet finish. A surface roughness of 0.8 to 1.5 μm (30 to 60 $\mu\text{in.}$) for average peak height and two to six peaks per millimeter (50 to 150 peaks per inch) is considered standard for cold-rolled steel sheet. The surface finish is determined by the finish applied to the cold-mill rolls and the temper-mill rolls. Roll finishes are obtained by shot blasting or electroetching a ground roll surface so that the roll is roughened sufficiently to transfer the pattern to the sheet. As these rolls are used, their finish tends to become smoother; there may be a consequent change in appearance among coils, and press performance may vary slightly. A rougher sheet surface tends to hold lubricant better and resists galling and cold welding to die surfaces during forming. For parts requiring little forming, a smoother and often preferred finish can be attained when roughness is minimized.

Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Correlation Between Microstructure and Formability

The formability of steel sheet is related to various microstructural features of the sheet. For example, grain size and shape, grain orientation relative to the rolling direction, and the various microconstituents present in the steel are reflected in its forming behavior.

Grain size of steel sheet influences formability in two opposing ways. Petch (Ref 3) has shown that the yield strength of low-carbon steel varies inversely with the square root of the grain diameter. Fine-grained steels are quite strong, but they have low strain-hardening exponents and limited formability. Blickwede (Ref 4) has shown (Fig. 6) that r_m decreases as grain size decreases. Coarse-grained steels have better formability, but the roughened surface (called orange peel) that results from stretching steel with grain sizes that are below ASTM 5 is unacceptable for many applications. Grain sizes of

ASTM 7 or 8 are usually a good compromise between formability and surface appearance. High-strength low-alloy steels, however, are usually produced with extremely small grain sizes (as small as ASTM 12) to increase both strength and toughness.

Fig. 6 Variation in r_m with grain size for four low-carbon sheet steels. Steels were cold reduced 70% and annealed. Source: Ref 4

Figure 7 shows the effect of abnormally large surface grains on surface appearance after forming. It should be noted that the effect of the large surface grains is visible on the opposite surface of the sheet.

Fig. 7 Forming behavior of decarburized rimmed steel sheet (1.12 mm, or 0.044 in., thick) containing normal grain size distribution and abnormally large surface grains, which resulted from a change from normal manufacturing practice. (a) Cross section of test cup made from normally manufactured steel sheet. Grain size ASTM 6 throughout. (b) Cross section of test cup made from steel sheet containing abnormally large surface grains. Grain size ASTM 3 at one surface and ASTM 7 elsewhere. (a) and (b) both 100×, 3% nital etch. (c) Outside surface of test cup made from normally manufactured steel sheet. (d) Outside surface of test cup made from steel sheet having abnormally large grains on outside surface of cup. Note pronounced orange peel effect. (e) Outside surface of test cup made from steel sheet having abnormally large grains on inside surface of cup.

(c), (d), and (e) all $\frac{2}{3} \times$

Grain shape of the ferrite can also affect sheet formability. Rimmed and hot-rolled aluminum-killed steels generally have equiaxed grains. Cold-rolled aluminum-killed steels, when properly processed, generally exhibit pancake-shape ferrite grains (Fig. 8). This grain shape is associated with the preferred grain orientation that is responsible for the excellent formability of aluminum-killed steels.

Fig. 8 Low-carbon steel, cold rolled 65%, showing the grain structure in the rolling plane (R), the longitudinal

plane (*L*), and the transverse plane (*T*). RD, rolling direction

The microconstituents that are found in low-carbon steel at room temperatures include iron carbides and various nonmetallic inclusions. The most common inclusions are sulfides, silicates, and oxides. Aluminum-killed steels will also contain submicroscopic particles of aluminum nitrides.

These microconstituents can affect the formability of steel sheet by altering its strength. Alloying elements that dissolve in ferrite strengthen the steel appreciably, thereby reducing its formability. Nonmetallic inclusions may form a distinctive pattern of stringers that reflects the processing history from ingot to sheet. These elongated particles affect the formability of sheet primarily because they encourage cracking at the edge of a part during forming.

Sheet Formability of Steels

Revised by W.G. Granzow, Armco, Inc., Research & Technology

Effect of Metallic Coatings on Formability

Low-carbon steels are often coated with zinc, aluminum, or terne to improve their resistance to corrosion. The coating may be applied by submerging the steel in a container filled with the molten metal (hot-dipped) or by electroplating. The formability of these coated steels is the same as the formability of the base metal to which they are applied, modified by the frictional effects and handling problems imposed by the coating.

The base metal for electrogalvanized and terne-coated steels is normally processed in the same manner as uncoated steel base metal, and the mechanical properties are the same. However, zinc and aluminum hot-dipped coated steels are processed in continuous annealing lines, and this treatment affects the mechanical properties and the formability of the base metal. Conventional commercial-quality (CQ), drawing-quality (DQ), and drawing-quality special-killed (DQSK) hot-dipped coated steels will exhibit higher yield and tensile strengths, higher hardness, lower elongation, and lower *r* values than uncoated low-carbon steels, and they will generally have poorer formability. Decarburized hot-dipped coated steels (sometimes referred to as IF or DDQSK grades) are not similarly affected by the continuous annealing process, and these grades usually have somewhat better mechanical properties and formability than uncoated low-carbon steels.

The coatings can be slippery or abrasive. A terne coating is often applied on difficult parts because of its excellent lubricity. Because many hot-dipped zinc coatings are slippery, they may require slightly more blank holder pressure during press forming than do uncoated steels. Aluminum coatings and electrogalvanized coatings tend to develop higher friction during forming and thus generally require better lubrication than uncoated steels.

All steel coatings are softer than the steel base metal and can be scraped or gouged off the base metal surface with sharp burrs on blank edges or rough areas in the processing equipment. Coating that is scraped off tends to build up on the tooling (flaking), thereby producing a poor surface on the formed part. The solution is to maintain sharp cutting edges on blanking tools to minimize burr height, as well as a polished surface in die contact areas. Flaking can also be controlled with improved lubrication practice.

Gray cast iron dies, in particular, cause flaking problems. Ideally, cast tooling that is to be used to press form a coated steel should be made of cast steel or nodular cast iron. However, flaking problems in gray cast iron tooling can be eliminated by chrome plating or ion nitriding the tool contact surfaces.

Selection of Steel Sheet

Steel sheet selection should be based on an understanding of available grades of sheet and forming requirements. Other factors that should be considered when selecting a material for forming into a particular part include:

- Purpose of the part and its service requirements
- Thickness of the sheet metal and allowable tolerances
- Size and shape of blanks for the forming operation
- Equipment available for forming
- Quantities required
- Available handling equipment for sheets or coils
- Local availability of sheet products
- Surface characteristics of the steel sheet
- Special finishes or coatings for appearance or for corrosion resistance
- Aging propensity and its relation to time before use
- Strength of the steel sheets as-delivered
- Strength requirements in the formed part

Because these factors may be interdependent and large quantities are generally used in part manufacture, it is often desirable that steel selection be made after consultation with either the technical representatives of suppliers or the steel producer. Some parts require specialized low-carbon steel that has been processed to enhance a given mechanical property. These are other less critical formed parts that can use a wide selection of both hot-rolled and cold-rolled steel sheet. The user and producer should understand not only how steels are produced but what a steel mill can do to obtain specific properties in order to prevent the purchase of a steel possessing unwanted properties. The user should be aware of special steels that, although more costly, may reduce production costs and forming problems, resulting in per-part savings.

Low-carbon steels, coated and uncoated, are generally supplied as commercial-quality, drawing-quality, and drawing-quality special-killed grades. Some steel mills also offer specialized grades, such as interstitial-free deep-drawing steels and enameling steels. Some of the forming characteristics of the more commonly used formable grades are:

- *Commercial quality*: Available in hot-rolled, cold-rolled, and coated grades. The least expensive grade of sheet steel. Subject to aging (mechanical properties may deteriorate with time). Not intended for difficult-to-form shapes
- *Drawing quality*: Available in hot-rolled, cold-rolled, and coated grades. Exhibits better ductility than CQ grade steels, but has low r values. Subject to aging (mechanical properties may deteriorate with time). Has excellent base metal surface quality
- *Drawing-quality special-killed*: Available in hot-rolled, cold-rolled, and coated grades, with good forming capabilities. Not subject to aging (mechanical properties do not change with time)
- *Interstitial-free steels*: Available in cold-rolled and coated grades, with excellent forming capabilities. Not subject to aging (mechanical properties do not change with time)
- *Enameling steels*: Available in cold-rolled grades. Various types of processing are used to make a product that is satisfactory for porcelain enameling. All grades have good forming capabilities
- *Higher-strength steel sheets*: Available in hot-rolled, cold-rolled, and coated grades. Various types of processing are used to obtain the desired strength levels. In general, the formability of these grades decreases as yield strength increases. Springback may be a problem at lower sheet thicknesses

Steel sheet selection can be assisted by circle grid analysis, which provides a reliable description of the strain condition in press-formed shapes and which indicates whether the steel is capable of making the required shape or whether a more formable grade is required. Also, if a circle grid analysis shows severe strains with good-quality sheet steel that has normal mechanical properties, this is a strong indication that some modifications will have to be made in the forming process if production is to be maintained. By accurately identifying the problem areas in sheet metal forming operations, circle grid analysis can produce significant savings for both the manufacturers and the users of steel sheet.

Bulk Formability of Steels

Introduction

BULK FORMABILITY, also known as workability, refers to the relative ease with which a metal can be shaped through deformation processes such as forging, extrusion, or rolling. Bulk formability is related to sheet formability in only the broadest sense, in that both characteristics provide quantitative estimates of the strength and ductility of a metal. The latter property--ductility, or the resistance of the material to failure--is usually of primary concern in describing both bulk and sheet formability.

Formability Characteristics

Bulk Versus Sheet Formability. To clarify the distinction between bulk formability and sheet formability, it may be useful to compare and contrast the types of deformation that occur during typical bulk and sheet forming processes.

In both processes, the surfaces of the deforming metal are in contact with forming tools, and friction may have a major influence on material flow. In bulk forming, the surface-to-volume ratio of the formed part increases considerably under the action of largely compressive stresses. Plastic deformation is much more prevalent than elastic deformation; therefore, elastic recovery after deformation is negligible. Important material characteristics include flow stress, failure behavior, and the metallurgical transformations that characterize the alloy system in question.

In sheet forming operations, the metal is plastically deformed by tensile loads, often without significant changes in sheet thickness or surface characteristics. The magnitudes of plastic and elastic deformation may be similar, resulting in a significant amount of elastic recovery or springback. A key characteristic of a material is the plastic-strain ratio r , the resistance of the sheet to thinning during deformation.

The major emphasis in determining both the bulk formability and sheet formability of materials is on measuring and predicting the limits of deformation before fracture. A useful tool for graphically depicting the bulk formability of a material is the workability diagram, which indicates the locus of normal free-surface strains that result in fracture. The analogous concept for sheet formability is the forming limit diagram.

Tests for Bulk Formability. Both of these graphic depictions of formability rely on data gathered from laboratory formability tests. A wide variety of tests are used to determine bulk formability, ranging from general tests (tension and torsion tests, for example) to specialized tests that have a very narrow scope and range of application. Test procedures commonly used for determining the bulk formability of steels are covered in the section "Formability Tests" in this article.

Bulk Formability of Carbon and Alloy Steels. Despite the large number of available compositions, all the materials in this category exhibit essentially similar bulk formability characteristics. Exceptions to this are steels containing free-machining additives such as sulfides; these materials are not as receptive to bulk forming as nonfree-machining grades (Fig. 1).

Fig. 1 Comparison of the bulk formability of carbon and low-alloy steels with the formability of resulfurized grades. T_M is the absolute melting temperature of the alloys. Source: Ref 1

Generally, the bulk formability of carbon and alloy steels improves as the deformation rate increases. The improvement has been primarily attributed to the increased heat of deformation generated at high deformation rates.

Because steels are the most commonly forged materials, a particularly important aspect of their bulk formability is forgeability, the ability to flow readily and fill forging die recesses without fracturing. An important measure of forgeability is flow stress, the amount of force required to deform the material at a specific temperature and strain rate. The section "Evaluating Forgeability" in this article includes information on measuring flow stress.

This article will present procedures for various formability tests used for carbon and alloy steels. The metallurgy and thermomechanical processing of high-strength low-alloy (microalloyed) steels will also be discussed.

Formability Tests

Tests for bulk formability can be divided into two main categories: primary tests and specialized tests. Primary tests such as tension and torsion tests have somewhat limited utility; specialized tests more closely simulate the deformation experienced in actual bulk forming processes and may give better indications of formability.

Primary Tests

The primary tests for workability are those for which the stress state is well known and controlled. Generally, these are small-scale laboratory simulation tests.

The tension test is widely used to determine the mechanical properties of a material (Ref 1). Uniform elongation, total elongation, and reduction in area at fracture are frequently used as indices of ductility. However, the extent of deformation possible in a tension test is limited by the formation of a necked region in the tension specimen. This introduces a triaxial tensile stress state and leads to fracture. For carbon and alloy steels, tension tests are primarily used under special high strain rate, hot tension test conditions to establish the range of hot-working temperatures. The principal advantage of hot tension testing for carbon and alloy steels is that minimum and maximum hot-working temperatures are clearly established.

Most commercial hot tensile testing is done with a Gleeble unit, which is a high strain rate, high-temperature testing machine (Ref 2). A solid buttonhead specimen that has a reduced diameter of 6.35 mm (0.250 in.) and an overall length of 88.9 mm (3.5 in.) is held horizontally by water-cooled copper jaws (grips), through which electric power is introduced to resistance heat the test specimen (Fig. 2). Specimen temperature is monitored by a thermocouple welded to the specimen surface at the middle of its length. The thermocouple, with a function generator, controls the heat fed into the specimen according to a programmed cycle. Therefore, a specimen can be tested under time and temperature conditions that simulate hot-working sequences.

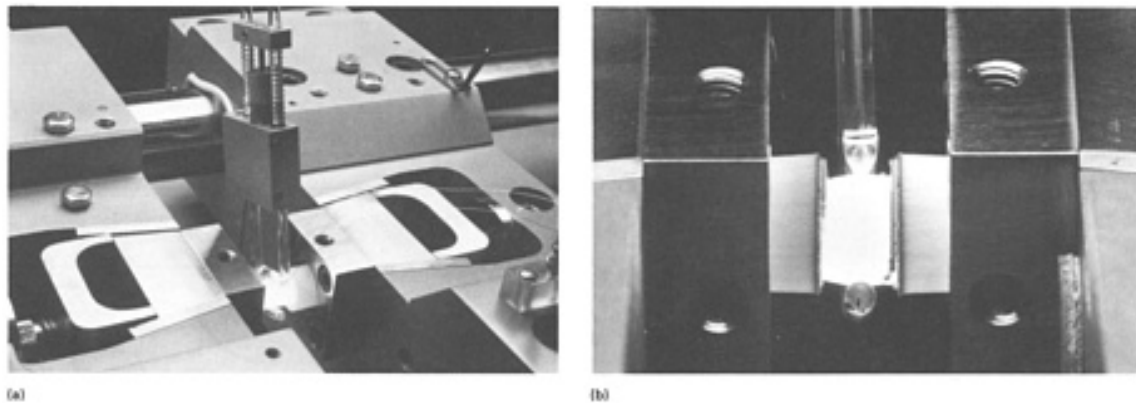

Fig. 2 Gleeble test unit used for hot tension and compression testing. (a) Specimen in grips showing attached thermocouple wires and linear variable differential transformer (LVDT) for measuring strain. (b) Close-up of a test specimen. Courtesy of Duffers Scientific, Inc.

The specimen is loaded by a pneumatic-hydraulic system. The load can be applied at any time in the thermal cycle. Temperature, load, and crosshead displacement are measured as a function of time.

The percent reduction in area is the primary result obtained from the hot tension test. This measure of ductility is used to assess the ability of the material to withstand crack propagation. Reduction in area adequately detects small ductility variations in materials caused by composition or processing when the material is of low-to-moderate ductility. It does not reveal small ductility variations in materials of very high ductility.

In the torsion test, deformation is caused by pure shear, and large strains can be achieved without the limitations imposed by necking (Ref 3). Because the strain rate is proportional to rotational speed, high strain rates are easily obtained. Moreover, friction has no effect on the test, as it does in compression testing. The stress state in torsion may represent the typical stress in metalworking processes, but deformation in the torsion test is not an accurate simulation of metalworking processes, because of excessive material reorientation at large strains.

Fracture data from torsion tests are usually reported in terms of the number of twists to failure or the surface fracture strain to failure. Figure 3 shows the relative hot workability of two AISI carbon and alloy steels as indicated by the torsion test. The test identifies the optimal hot-working temperature for each of the two steels. The section "Evaluating Forgeability" in this article contains information on the use of torsion testing to evaluate the forgeability of carbon and alloy steels.

Fig. 3 Ductility of two AISI carbon and alloy steels determined in hot torsion tests. Arrows denote suitable hot-working temperatures.

The compression test, in which a cylindrical specimen is upset into a flat pancake, is usually considered to be a standard bulk formability test. The average stress state during testing is similar to that in many bulk deformation processes, without introducing the problems of necking (in tension) or material reorientation (in torsion). Therefore, a large amount of deformation can be achieved before fracture occurs. The stress state can be varied over wide limits by controlling the barreling of the specimen through variations in geometry and by reducing friction between the specimen ends and the anvil with lubricants.

Compression testing has developed into a highly sophisticated test for formability in cold upset forging, and it is a common quality control test in the hot forging of carbon and alloy steels. Compression forging is a useful method of assessing the frictional conditions in hot working. The principal disadvantage of the compression test is that tests at a constant, true strain rate require special equipment.

Ductility Testing. The basic hot ductility test consists of compressing a series of cylindrical or square specimens to various thicknesses or to the same thickness with varying specimen length-to-diameter (length-to-width) ratios. The limit for compression without failure by radial or peripheral cracking is considered to be a measure of bulk formability. This type of test has been widely used in the forging industry. Longitudinal notches are sometimes machined into the

specimens before compression. Because the notches apparently cause more severe stress concentrations, they enable the test to provide a more reliable index of the workability to be expected in a complex forging operation.

The bend test is useful for assessing the formability of thick steel sheet and plate. Generally, this test is most applicable to cold-working operations. The principal stress and strains developed during bending are defined in Fig. 4. The critical parameter is the width-to-thickness ratio, w/t . If $w/t > 8$, bending occurs under plane-strain conditions ($\epsilon_2 = 0$) and $\sigma_2/\sigma_1 = 0.5$. If $w/t > 8$, the bend ductility is independent of the exact w/t ratio. If $w/t < 8$, then the stress state and bend ductility depends strongly on the width-to-thickness ratio.

Fig. 4 Bend region defining the direction of principal stresses and strains in bend testing

Specialized Tests

In the plane-strain compression test, the specimen is a thin plate or sheet that is compressed across the width of the strip by narrow platens that are wider than the strip. The elastic constraints of the undeformed shoulders of material on each side of the platens prevent extension of the strip in the width dimension; hence the term plane strain.

Deformation occurs in the direction of platen motion and in the direction normal to the length of the platen. To ensure that lateral spread is negligible, the width of the strip should be at least six to ten times the breadth of the platens. To ensure that deformation beneath the platens is essentially homogeneous, the ratio of platen breadth to strip thickness, b/t , should be between 2 and 4 at all times. It may be necessary to change the platens during testing to maintain this condition. True strains of 2 can be achieved by carrying out the test in increments in order to provide good lubrication and to maintain the proper b/t ratio. Because of its geometry, this test is more applicable to rolling operations than to forging.

The partial-width indentation test is similar to the plane-strain compression test, but it does not subject the test specimen to true plane-strain conditions (Ref 4). In this test, a simple slab-shaped specimen is deformed over part of its width by two opposing rectangular anvils having widths smaller than that of the specimen. Upon penetrating the workpiece, the anvils longitudinally displace metal from the center, creating over-hangs (ribs) that are subjected to secondary, nearly uniaxial tensile straining. The material ductility under these conditions is indicated by the reduction in the rib height at fracture. The test geometry has been standardized.

One advantage of this test is that it uses a specimen of simple shape; another is that as-cast materials can be readily tested. One edge of the specimen can contain original surface defects. The test can be conducted hot or cold.

The secondary-tension test is a modification of the partial-width indentation test. In this test, a hole or a slot is machined in the slab-type specimen adjacent to where the anvils indent the specimen. With this design, the ribs are sufficiently stretched to ensure fracture in even the most ductile materials. The fracture strain is based on reduction in area where the rib is cut out so that the fracture area can be photographed or traced on an optical comparator.

Ring Compression Test. When a flat ring-shaped specimen is upset in the axial direction, the resulting change in shape depends only on the amount of compression in the thickness direction and the frictional conditions at the die/ring interfaces. If the interfacial friction were zero, the ring would deform in the same manner as a solid disk, with each element flowing outward radially at a rate proportional to its distance from the center.

In the case of small, but finite, interfacial friction, the outside diameter is smaller than in the zero-friction case. If the friction exceeds a critical value, frictional resistance to outward flow becomes so high that some of the ring material flows inward to the center. Measurements of the inside diameters of compressed rings provide a particularly sensitive means of studying interfacial friction because the inside diameter increases if the friction is low and decreases if the friction is higher. The ring test, then, is a compression test with a built-in frictional measurement. Therefore, it is possible to measure the ring dimensions and compute both the friction value and the basic flow stress of the ring material at the strain under the given deformation conditions.

The ring compression test, can be used to measure the flow stress under high-strain practical forming conditions. The only instrumentation required is that for measuring the force needed to produce the reduction in height.

Bulk Formability of Steels

Evaluating Forgeability

The hot forging of carbon and alloy steels into intricate shapes is rarely limited by forgeability aspects, with the exception of the free-machining grades mentioned earlier. Section thickness, shape complexity, and forging size are limited primarily by the cooling that occurs when the heated workpiece comes into contact with the cold dies. For this reason, equipment that has relatively short die contact times, such as hammers, is often preferred for forging intricate shapes in steel.

Because forging is a complex process, a single test cannot be relied on to determine forgeability. However, several testing techniques have been developed for predicting forgeability, depending on alloy type, microstructure, die geometry, and process variables. This section will summarize some of the common tests for determining formability in open-die and closed-die forgings.

Forgeability

Hot Twist Testing. One common means of measuring the forgeability of steels is the hot twist test. As the name implies, this test involves twisting heated bar specimens to fracture at a number of different temperatures selected to cover the possible hot-working temperature range of the test material. The number of twists to fracture and the torque required to maintain twisting at a constant rate are reported. The temperature at which the number of twists is the greatest, if such a maximum exists, is assumed to be the optimal hot-working temperature of the test material. Figure 5 shows the forgeabilities of several carbon steels as determined by hot twist testing. More information on the hot twist test is available in Ref 5, 6, and 7.

Fig. 5 Forgeabilities of various carbon steels as determined using hot twist testing. Source: Ref 5

Wedge-Forging Test. In this test, a wedge-shaped piece of metal is machined from a cast ingot or wrought billet and forged between flat, parallel dies (Fig. 6). The dimensions of the wedge must be selected so that a representative structure of the ingot is tested. Coarse-grain materials require larger specimens than fine-grain materials. The wedge-forging test is a gradient test in which the degree of deformation varies from a large amount at the thick end (h_2) to a small amount or no deformation at the thin end (h_1). The specimen should be used on the actual forging equipment in which production will occur to allow for the effects of deformation velocity and die chill on workability.

Fig. 6 Specimen for the wedge-forging test. (a) as-machined specimen. (b) Specimen after forging

Tests can be made at a series of preheat temperatures, beginning at about nine-tenths of the solidus temperature or the incipient melting temperature. After testing at each temperature, the deformation that causes cracking can be established. In addition, the extent of recrystallization as a function of strain and temperature can be determined by performing metallographic examinations in the direction of the strain gradient.

The sidepressing test consists of compressing a cylindrical bar between flat, parallel dies where the axis of the cylinder is parallel to the surfaces of the dies. Because the cylinder is compressed on its side, this testing procedure is termed sidepressing. This test is sensitive to surface-related cracking and to the general unsoundness of the bar because high tensile stresses are created at the center of the cylinder.

For a cylindrical bar deformed against flat dies, the tensile stress is greatest at the start of deformation and decreases as the bar assumes more of a rectangular cross section. The degree of tensile stress can be reduced at the outset of the tests by changing from flat dies to curved dies that support the bar around part of its circumference.

The typical sidepressing test is conducted with unconstrained ends. In this case, failure occurs by ductile fracture on the expanding end faces. If the bar is constrained to deform in plane strain by preventing the ends from expanding, deformation will be in pure shear, and cracking will be less likely. Plain-strain conditions can be achieved if the ends are blocked from longitudinal expansion by machining a channel or cavity into the lower die block.

The notched-bar upset test is similar to the conventional upset test, except that axial notches are machined into the test specimens. The notched-bar test is used with materials of marginal forgeability for which the standard upset test may indicate an erroneously high degree of workability. The introduction of notches produces high local stresses that induce fracture. The high levels of tensile stress in the test are believed to be more typical of those occurring in actual forging operations.

Test specimens are prepared by longitudinally quartering a forging billet, thus exposing center material along one corner of each test specimen. Notches with 1.0 or 0.25 mm (0.04 or 0.01 in.) radii are machined into the faces. A weld button is frequently placed on one corner to identify the center and surface material of alloys that are difficult to forge because of segregation.

Specimens are heated to predetermined temperatures and upset about 75%. The specimen is oriented with the grooves (notches) in the vertical direction. Because of the stress concentration effect, ruptures are most likely to occur in the notched areas. These ruptures can be classified according to the rating system shown in Fig. 7. A rating of 0 indicates that no ruptures are observed, and higher numbers indicate an increasing frequency and depth of rupture.

Fig. 7 Suggested rating system for notched-bar upset test specimens that exhibit progressively poorer forgeability. A rating of 0 indicates freedom from ruptures in the notched area.

Truncated-Cone Indentation Test. This test involves the indentation of a cylindrical specimen by a conical tool. As a result of the indentation, cracking is made to occur beneath the surface of the testpiece at the tool/material interface. The reduction (measured at the specimen axis) at which cracking occurs can be used to compare the workability of different materials. Alternatively, the reduction (stroke) at which a fixed crack width is produced or the width of the crack at a given reduction can be used as a measure of workability.

The truncated cone was developed as a test that minimizes the effects of surface flaws and the variability they produce in workability (Ref 8). This test has been primarily used in cold forging.

Flow Localization

Complex forgings frequently develop regions of highly localized deformation. Shear bands may span the entire cross section of a forging and, in extreme cases, produce shear cracking. Flow localization can arise from constrained deformation due to die chill or high friction. However, flow localization can also occur in the absence of these effects if the metal undergoes flow softening or negative strain hardening.

Nonisothermal Upset Test. The simplest workability test for detecting the influence of heat transfer (die chilling) on flow localization is the nonisothermal upset test, in which the dies are much colder than the workpiece. Zones of flow localization must be made visible by sectioning and metallographic preparation.

The sidepressing test conducted in a nonisothermal manner can also be used to detect flow localization. Several test specimens are sidepressed between flat dies at several workpiece temperatures, die temperatures, and working speeds. The formation of shear bands is determined by metallography. Flow localization by shear band formation is more likely in the sidepressing test than in the upset test. This is due to the absence of a well-defined axisymmetric chill zone. In the sidepressing of round bars, the contact area starts out as 0 and builds up slowly with deformation. In addition, because the deformation is basically plane strain, surfaces of zero extension are present, along which block shearing can initiate and propagate. These are natural surfaces along which shear strain can concentrate into shear bands.

Flow Stress and Forging Pressure

Flow stresses and forging pressures can be obtained from torque curves generated in hot twist tests or from hot compression or tension testing. Figure 8 shows torque versus temperature curves for several carbon and alloy steels obtained from hot twist testing. These data show that the relative forging pressure requirements for this group of alloys do not vary widely at normal hot-forging temperatures. A curve for AISI type 304 stainless steel is included to illustrate the effect of higher alloy content on flow strength.

Fig. 8 Deformation resistance versus temperature for various carbon and alloy steels. Source: Ref 9

Figure 9 shows actual forging pressure measurements for 1020 and 4340 steels and AISI A6 tool steel for reductions of 10 and 50%. Forging pressures for 1020 and 4340 vary only slightly at identical temperatures and strain rates. Considerably greater pressures are required for the more highly alloyed A6 material, and this alloy also exhibits a more significant increase in forging pressure with increasing reduction.

Fig. 9 Forging pressure versus temperature for three steels. Data are shown for reductions of 10 and 50%; strain rate was constant at 0.7 s^{-1} Source: Ref 10

Flow Stress in Compression. Ideally, the determination of flow stress in compression should be carried out under isothermal conditions (no die chilling) at a constant strain rate and with a minimum of friction in order to minimize barreling. These conditions can be met with conventional servohydraulic testing machines.

In flow stress determination, a specific load is applied to a cylindrical specimen of known height, the load is removed, and the new height is determined in order to calculate a true strain. Upon relubrication, the specimen is subjected to an increased load, unloaded, and measured. The cycle is then repeated.

Microalloyed Steels*

Microalloying--the use of small amounts of elements such as vanadium and niobium to strengthen steels--has been in practice since the 1960s to control the microstructure and properties of low-carbon steels. Most of the early developments were related to plate and sheet products in which microalloy precipitation, controlled rolling, and modern steelmaking technology were combined to increase strength significantly relative to that of other low-carbon steels.

The application of microalloying technology to forging steels has lagged behind that of flat-rolled products because of the different property requirements and thermomechanical processing of forging steels. Forging steels are commonly used in applications in which high strength, fatigue resistance, and wear resistance are required. These requirements are most often filled by medium-carbon steels. Thus, the development of microalloyed forging steels has centered on grades containing 0.30 to 0.50% C.

Regardless of product form (plate, bar, or forging), microalloyed steels are a classic example of a successful metallurgical innovation in which alloying additions and thermomechanical processing have been brought together effectively to attain improved combinations of engineering properties through microstructural control. This practice is relatively inexpensive because only small concentrations of the alloying elements (typically niobium, vanadium, or titanium) are needed to form carbides or carbonitrides. Where possible, the associated thermomechanical processing is introduced merely as a modification of the final hot-working operation. Although precipitation hardening with fine carbonitrides and substructural changes due to warm rolling of austenite-ferrite mixtures can contribute to the strengthening of microalloyed steels, the microstructural feature that ultimately provides a favorable balance of strength and toughness is a small ferritic grain size.

The following sections compare the processing of microalloyed plate and bar products. More information on the metallurgy and properties of microalloyed steel forgings is available in the article "High-Strength Low-Alloy Steel Forgings" in this Volume.

Processing of Microalloyed Plate Steels

Figure 10 shows a temperature-time profile for the rolling of 19 mm ($\frac{3}{4}$ in.) microalloyed steel plate. Initially, slabs are reheated to temperatures in the range of 1100 to 1250 °C (2010 to 2280 °F). The rolling operation itself generally involves two distinct stages: high-temperature rolling or roughing and a lower-temperature series of deformation steps designated as finishing. If the roughing and finishing operations are continuous, the process is termed hot rolling, but if there is a delay between the two stages, as shown in Fig. 10, the process is referred to as controlled rolling. After rolling, the plate is usually air cooled, although a recently developed technology involves water spray cooling of the plate after finish rolling.

Fig. 10 Temperature-time profile for controlled rolling of 19 mm ($\frac{3}{4}$ in.) thick microalloyed steel plate. T_R , recrystallization temperature

Overall, the plate-rolling operation lends itself to considerable control of the thermomechanical treatment. The slab reheat temperature can be reduced if desired. In fact, some rolling strategies involve only reheating to 960 °C (1760 °F) prior to rolling. Delays can be built into the rolling operation (although with some penalty in productivity), and a considerable range of finishing temperatures can be achieved. This operation can accommodate the most severe controlled-rolling schedules, including the deformation of austenite-ferrite mixtures.

In metallurgical terms, the controlled-rolling operation in microalloyed steels serves two purposes. The first is to refine the relatively coarse, as-reheated austenitic microstructure by a series of high-temperature rolling and recrystallization steps. The second purpose of the rolling operation is to impose a moderate-to-heavy reduction in a temperature regime where austenite recrystallization is inhibited between rolling passes (below the recrystallization temperature indicated in Fig. 10) such that the plastically deformed austenite grains remain pancaked. Subsequent transformation after rolling into ferritic microstructures results in the desired fine grain size and associated mechanical properties. The various parts of the rolling operation are discussed separately and in greater detail in the following sections of this article.

Thermomechanical Treatment (Rolling). Typically, the initial rolling passes are conducted at relatively high temperatures, just below the slab-reheating temperature. At these temperatures, each deformation step is usually followed by rapid recrystallization and grain growth. Recently, a thermomechanical processing procedure called recrystallization controlled rolling has been proposed. It combines repeated deformation and recrystallization steps with the addition of austenite grain-growth inhibitors such as titanium nitride to refine the starting austenitic grain size and to restrict grain growth after recrystallization. Such processing would obviate the need for low-temperature controlled rolling (Ref 11, 12, 13). However, even with optimum compositions and the adoption of rather difficult reduction schedules, there seems to be a limit to the degree of austenitic refinement that can be achieved by repeated recrystallization; the finest recrystallized austenitic grain sizes produced by this process are about 15 μm (600 $\mu\text{in.}$). Depending on the subsequent cooling rate, transformation can then result in a ferritic grain size of 6 to 8 μm (240 to 320 $\mu\text{in.}$) (Ref 13). This is useful degree of structural refinement and is appropriate in those cases where controlled rolling is not possible (for example, due to mill load constraints).

However, still finer grain sizes can be attained through the use of additional microalloying elements along with a controlled-rolling sequence in which austenite recrystallization is substantially retarded during the later rolling passes. This process develops a pancaked grain morphology and a much higher surface area per unit volume than are possible in recrystallized austenite (Ref 14). During this process, the austenite recrystallization and carbonitride precipitation reactions are coupled in the sense that each is greatly influenced by the other.

Transformation to Ferrite. The transformation of the austenite grain into ferritic microstructures determine the final grain size and associated mechanical properties of the microalloyed plate. The effects of austenitic morphology and the transformation temperature range (as governed by alloy content, rolling deformation, and cooling rate) are of the greatest importance. Even after the minimum austenitic grain thickness has been produced, the temperature range of the austenite-to-ferrite transformation must be controlled to determine the reaction kinetics. Increasing the ferritic nucleation rate and decreasing the ferritic growth rate can produce a finer ferritic grain size. These effects are generally achieved by alloying or controlled cooling.

Precipitation and Substructural Strengthening. Although grain refinement offers the best combination of strength and toughness, there is a practical limit to the yield strength level that can be achieved with this strengthening mechanism alone: about 450 MPa (65 ksi) for a grain size of 3 μm (120 $\mu\text{in.}$). For higher strength levels, additional strengthening mechanisms must be used; however, these mechanisms can have deleterious effects on toughness (Ref 15). For example, as vanadium is added to a controlled-rolled niobium-containing microalloyed plate steel, the yield strength is increased about 7 MPa (1 ksi) for every 0.01% increase in vanadium. This strengthening is due to the precipitation of vanadium-rich carbonitrides in the ferrite during air cooling of the plate after rolling. For a typical vanadium content of 0.10%, this precipitation strengthening can raise the yield strength to about 525 MPa (76 ksi). This results in the deformation of austenite-ferrite mixtures and the development of a warm-worked ferritic substructure. As shown in Fig. 11, strength increases progressively as rolling is continued to lower temperatures. At the same time, toughness is also reduced; therefore, this strengthening mechanism is used in microalloyed steels mainly as a way to reach the last increment of required strength.

Fig. 11 Yield strength of a microalloyed steel as a function of finishing temperature. Grain size: 5 μm (200 $\mu\text{in.}$). Source: Ref 16

High-Strength Low-Alloy (HSLA) Plate Products. The basic metallurgical principles discussed above are used to produce a range of as-rolled microalloyed plate steels at thicknesses to 102 mm (4 in.) and yield strengths as high as 550 MPa (80 ksi). In these steels, niobium is added to control the recrystallization temperature, manganese is often used to control austenite formation, and vanadium is introduced for precipitation strengthening. Finish rolling is carried out at temperatures low enough to produce substructural strengthening.

Processing of Microalloyed Bars

In contrast to the plate-rolling process, the thermomechanical treatment possible on a modern bar mill (Fig. 12) is somewhat limited in scope. For example, the temperature-time profile for the rolling of 44 mm ($1\frac{3}{4}$ in.) diam bar shown in Fig. 13 can be compared to the plate-rolling profile shown in Fig. 10. There are clear differences between these rolling processes:

- Lower reheat temperatures, typically in the range of 1100 to 1200 °C (2010 to 2190 °F), are used in bar rolling. This lower temperature, in combination with the generally higher carbon levels in bar products, limits the amount of niobium that can be dissolved upon reheating. For example, in a 0.20% C steel, only about 0.01% Nb is soluble at 1100 °C (2010 °F). In contrast, vanadium is still readily soluble at bar reheat temperatures. Consequently, in HSLA bar grades, vanadium is the microalloying element commonly used to obtain to the highest possible strength levels
- Even though the lower reheat temperatures typical of bar products place some limitations on the use of different microalloying elements, these lower temperatures do provide for a finer as-reheated austenitic grain size than is typical of slabs reheated for conversion to plate. With a small titanium addition and continuous casting, as-reheated austenitic grain sizes of 50 to 60 μm (0.0020 to 0.0024 in.) can be achieved in billets destined for bar
- Finishing temperatures in bar rolling are relatively high, even with the use of interstand cooling

Consequently, recrystallization controlled rolling becomes quite important in bar rolling, and the rolling strategy must be designed to produce the finest possible recrystallized austenitic grain size. Subsequent control of the austenite-to-ferrite transformation range is still important to maximize ferritic grain refinement. Nevertheless, as discussed earlier for plate, the ferritic grain size that can be produced on transformation from a recrystallized austenite is limited compared to the grain size that can be produced on transformation from austenitic grains that have been flattened by rolling below the recrystallization temperature. Thus, while moderate grain refinement can be achieved in an as-rolled microalloyed bar, this grain size will be somewhat coarser than the grain size of controlled-rolled HSLA plates.

Fig. 13 Temperature-time profile for the controlled rolling of 44 mm ($1\frac{3}{4}$ in.) diam microalloyed steel bar. Compare with Fig. 10.

Alternative Strengthening Mechanisms in Microalloyed Bar Steels. Because the degree of ferritic grain refinement possible in as-rolled microalloyed bar steels is somewhat limited, and because substructural strengthening is not possible, alternative strengthening mechanisms must be employed to reach yield strength levels comparable to those of plate grades. For example, in the alloy design of microalloyed bar steels, precipitation and pearlite strengthening must be relied on to a greater extent than in the design of plates. In view of the limited solubility of niobium or titanium at the reheat temperatures used in bar processing, vanadium is usually used to obtain the required level of precipitation strengthening in HSLA bar grades. Precipitation of V(C,N) during or after transformation can provide significant strengthening increments. In this regard, nitrogen level is also of importance. Judicious selection of both the vanadium and nitrogen levels is required to produce the desired level of precipitation strengthening. Similarly, an increase in the carbon content and thus the pearlite volume fraction of a bar steel can also be used to increase strength (Ref 18, 19, 20). In addition to moderate grain refinement, precipitation hardening with VN and an increase in the pearlite volume fraction can be used to produce yield strength levels up to 625 MPa (91 ksi) in microalloyed bars. Of course, these two strengthening mechanisms have very deleterious effects on toughness.

High-Strength Low-Alloy Bar Products. The alloy and process design principles discussed above are employed to produce a reasonable selection of as-rolled microalloyed bar steels. Yield strength levels up to 625 MPa (91 ksi) have been publicized, although the available yield strength level is influenced by bar thickness. In these steels, titanium is sometimes added to control austenitic grain growth (on reheating and after recrystallization during rolling), carbon and manganese can be balanced to control the transformation temperature range, vanadium and nitrogen are used for precipitation strengthening, and carbon is increased (as required) to raise the pearlite fraction of the ferrite and pearlite microstructural aggregate. Compared to the higher-carbon quenched and tempered grades that are currently used in competitive applications, these microalloyed bar steels offer comparable strength at lower cost because less alloy is required and heat-treating costs are eliminated. However, the toughness of the microalloyed bar grades developed to date is still somewhat lower than that of the higher-carbon, heat-treated steels. While the toughness levels currently available in commercial microalloyed bar steels may be adequate for many applications, considerable effort is being made at the present time to improve the toughness of microalloyed bar grades.

Comparison of Microalloyed Plate and Bar Products

The differing processing approaches for plate and bar are reflected in the microstructure and properties that are ultimately developed in these two product forms. Consider, as an example, the attributes of microalloyed plate and bar grades at the 550 MPa (80 ksi) yield strength level. The bar product (Fig. 14) has a coarser ferritic grain size and a significantly higher pearlite volume fraction (due to the higher carbon content) than the plate product. The comparison of compositions and yield-strengthening increments shown in Fig. 15 reflects these differences in microstructure. The most significant yield

strength increment in the plate product is due to ferritic grain refinement, while the bar product must rely more on precipitation strengthening. In both products, however, small strengthening contributions are required beyond the grain size and precipitation hardening level to reach a yield strength of 550 MPa (80 ksi). In plate, this increment is obtained by rolling to develop a ferritic substructure, while in bar a small contribution from pearlite is necessary. Of course, these different strengthening mechanisms have an impact on the toughness that can be achieved in these two product forms (Fig. 16). Because it has a finer ferritic grain size and relies less on precipitation strengthening, the plate product exhibits significantly better toughness than the bar product.

Processing of Microalloyed Forging Steels

The driving force behind the development of microalloyed forging steels has been the need to reduce manufacturing costs. This is accomplished in these materials by means of a simplified thermomechanical treatment (that is, a controlled cooling following hot forging) that achieves the desired properties without the separate quenching and tempering treatments required by conventional carbon and alloy steels.

Control of Properties. In order to realize the full strengthening potential of microalloying additions, it is necessary to use a soaking temperature prior to forging that is high enough to dissolve all vanadium-bearing precipitates. A soaking temperature above 1100 °C (2010 °F) is preferred. Rapid induction heating methods for bar and billet to conventional commercial forging temperatures of 1250 °C (2280 °F) are acceptable and allow sufficient time for the dissolution of the microalloying constituents.

Tensile strength decreases slightly as the finish forging temperature is reduced, but there is no significant effect on yield strength. Ductility and toughness show a significant increase with a reduction in finishing temperature; this is due to grain refinement of the austenite and increased ferrite content. Forgers are beginning to utilize this approach to enhancing the toughness of as-forged microalloyed steel; however, low finish forging temperatures are often avoided to minimize die wear. The specified properties of microalloyed forging steels can be achieved over a wide range of finishing temperatures.

One of the most important processing factors affecting the properties of as-forged microalloyed steels is the postforging cooling procedure. Increasing the cooling rate generally increases the yield and tensile strength because it enhances grain refinement and precipitation hardening. At high cooling rates, an optimum can be reached; above this rate the strength reduces due to the suppression of precipitation and the introduction of low-temperature transformation products.

The optimum cooling rate and maximum hardness are significantly influenced by the alloy and residual element content of the steel. Nevertheless, through control of the steel composition it is possible to ensure that the specified mechanical properties are achieved over a wide range of section sizes and cooling conditions.

Properties of Forged Parts. Because of the improved strength and hardness of microalloyed bar steels, it is possible to use them for the production of many forged parts and eliminate the need for subsequent heat treatment. This is particularly true when air cooling is applied to the as-forged parts. Numerous forgings weighing as little as 1 kg (3 lb) to well over 11 kg (25 lb) have been produced by this approach. The parts produced from microalloyed steel include connecting rods and caps, stub yokes, weld yokes, wheel hubs, stabilizer bars, blower shafts, sucker rods, anchor bolts, and U-bolts.

An example of the improved properties that can be obtained is shown in Fig. 17, in which the cross-sectional hardness of an air-cooled microalloyed 1541 forged part is compared with a similar quenched and tempered 1043 part. The hardness is much more uniform in the microalloyed part, and as a result the fatigue life at this location in the part is an order of magnitude greater than that in the quenched and tempered part.

Effects of Hot Mill Finishing Temperature (Ref 23). In tests of a grade of 1541 steel microalloyed with 0.10% V, higher hardness and tensile strengths were obtained with higher hot mill finishing temperatures (Fig. 18). Reduction in area also increased slightly at higher finishing temperatures. Yield strength and percent elongation values did not vary with finishing temperature over the range investigated. The steel finished at the lowest temperature (970 °C, or 1780 °F) had the highest impact strength in subsequent Charpy V-notch testing (Fig. 19).

Fig. 18 Effect of hot mill finishing temperature on hardness and tensile properties of 1541 steel containing 0.10% V. Source: Ref 23

Fig. 19 Effect of hot mill finishing temperature on impact properties of 1541 steel containing 0.10% V. Source: Ref 23

Effects of Forging Temperature. To achieve an optimum balance of strength and toughness properties, forged parts produced from microalloyed steel must be air-cooled through the transformation temperature. Slow cooling rates resulting from batch cooling must be avoided.

Because the forging process is the final thermal processing step in the production of parts from microalloyed chemistries, it is important that the forging operation be controlled in the same manner that the steelmaker controls the bar-rolling operation. The key forging variables that require process control are the reheating temperature and the postforging cooling rate (Ref 23).

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Introduction

THE MACHINABILITY OF CARBON AND ALLOY STEELS is affected by many factors, such as the composition, microstructure, and strength level of the steel; the feeds, speeds, and depth of cut; and the choice of cutting fluid and cutting tool material. These machining characteristics, in turn, affect the cost of producing steel parts, particularly when the cost of machining represents a major part of the cost of the finished part. This article describes the influence of the various attributes of carbon and alloy steels on machining characteristics.

It should be recognized that the relative cost of cutting two steels in a particular operation, such as boring, is not necessarily the same as the relative ease of cutting the same two steels in another operation, such as broaching. Machining processes differ in operational metal removal characteristics; some place a greater premium on high machinability of the workpiece than others. Several common machining processes are listed in approximate decreasing order of machinability requirement, as follows:

- Internal broaching
- External broaching
- Tapping
- Generation of gear teeth
- Deep drilling
- Boring
- Screw machining with form tools
- High-speed light-feed screw machining
- Milling
- Shallow drilling
- Planing and shaping
- Turning with single-point tools
- Sawing
- Grinding

The designer's choice of part shape and dimensions largely determines the selection of the machining process. The mechanical properties needed for satisfactory service performance usually dictate the selection of the workpiece material and condition of heat treatment. Consequently, decisions about materials by the manufacturing engineer are generally reduced to choosing between similar grades of steel (for example, between 4140 and 8640) rather than between very different grades (for example, 4140 and 12L14).

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Measures of Machinability

The term machinability is used to indicate the ease or difficulty with which a material can be machined to the size, shape, and desired surface finish. The terms machinability index and machinability rating are used as qualitative and relative measures of the machinability of a steel under specified conditions. There are no clear-cut or unambiguous meanings for these terms and no standard or universally accepted method of measuring machinability. Historically, machinability judgments have been based on one or more of the following criteria:

- *Tool life*: Measured by the amount of material that can be removed by a standard cutting tool under standard cutting conditions before tool performance becomes unacceptable or tool wear reaches a specified amount
- *Cutting speed*: Measured by the maximum speed at which a standard tool under standard conditions can continue to provide satisfactory performance for a specified period
- *Power consumption*: Measured by the power required to remove a unit volume of material under specified machining conditions
- Comparisons with a standard steel based on experience in machine shops
- Quality of surface finish
- Feeds resulting from a constant thrust force

Some of the test criteria are best suited to laboratory studies intended to elicit information about the effects of small changes in microstructure, composition, or processing history on machinability. Other types of tests are useful for studying the effects of geometry changes or cutting tool composition.

Years ago, machinability ratings were also relied upon as aids for choosing machining conditions to be used on materials unfamiliar to production personnel. This is rarely necessary now because detailed and reliable guides to suitable practices, such as the *Machining Data Handbook* (Ref 1), are readily available and widely used.

Tool life and cutting speed can be related by the equation:

$$V_c T^n = C_t \quad (\text{Eq 1})$$

where V_c is the cutting speed, T is the tool life, and n and C_t are empirical constants that reflect the cutting conditions under which the tests were made and the machinability of the material. In 1907, Taylor presented Eq 1 to describe single-point turning; the constant C_t is often called the Taylor constant. Because typical values of n for high-speed steel (HSS) tools range from 0.1 to 0.2, small variations in cutting speed are equivalent to enormous changes in tool life. Therefore, it is more practical to measure machinability as the cutting speed necessary to cause tool failure within a specified period, usually 60 min, than as tool life at a specified cutting speed. To determine the machinability of a particular steel, tool life for each of several cutting speeds (with standardized cutting conditions and tool shape) must be measured. Values of n and C_t can be determined from these data, and the cutting speed that corresponds exactly to the specified tool life can be calculated.

Tool life tests are used in laboratories to evaluate the effects of changes in tool materials, cutting variables, processing history, or workpiece compositions or microstructure on the ease of removing material. They are also useful for predicting tool life and choosing cutting speeds for industrial operations.

There are several criteria that can be used to define the failure of cutting tools. One criterion is the complete destruction of the cutting surface of the tool. A second criterion is the wear of the tool to the extent that the quality of the machined surface becomes unacceptable. Perhaps the most widely used criterion for tool failure is wear of the surface of the tool to some predetermined amount of flank wear. Sometimes, especially in screw machine tests, a specific increase in a part dimension is used to define tool life.

Regardless of the criterion adopted for tool failure, any machinability rating that depends on tool life measurements will be affected by the cutting tool. The choice of tool material, the configuration of the tool, the sharpness of the cutting edge, and the efficiency with which the tool is cooled can affect the machinability rating of the steel under test. For example, typical values of n for HSS tools range from 0.1 to 0.2; for carbide tools, typical values of n range from 0.2 to 0.4.

Therefore, machinability testing should be carefully standardized (as described in Ref 2 and 3) so that the test reflects the machinability of the material rather than variations in the test procedures.

Power Consumption. The forces acting on a tool during cutting, as measured on a dynamometer, can be used to estimate the power consumed in metal cutting. The power consumption (expressed in watts) in cutting operations is approximately equal to the product of the cutting speed, V_c (expressed in units of meters per second), and the component of the cutting force parallel to the cutting direction, F_c (expressed in newtons). In English units, this relation for power consumption is:

$$P = \frac{V_c \times F_c}{33000} \tag{Eq 2}$$

where P is power consumption (at the spindle) in horsepower units, F_c is the cutting force in pounds, and V_c is the cutting speed in feet per minute.

To calculate the unit power consumption, which reflects the power requirements for cutting a given quantity of a particular material, it is necessary to divide the power consumption, P , by the metal removal rate, Q (which is typically expressed in units of either cubic centimeters or inches per minute). Therefore, the unit power consumption, P_u , is:

$$P_u = \frac{P}{Q} \tag{Eq 3}$$

In cutting operations, $Q = d \cdot f \cdot V_c$, where d is the depth of cut and f is the feed rate. In metric units, the unit power consumption, P_u , is given by:

$$P_u = \frac{F_c}{fd} \tag{Eq 4}$$

where P_u is in joules per cubic centimeter, F_c is in newtons, and f and d are in millimeters. If F_c is given in pounds of force and f and d in inches, then P_u in horsepower per cubic inch per minute is given by:

$$P_u = \frac{2.525 \times 10^{-6} F_c}{fd} \tag{Eq 4a}$$

Typical data for unit power consumption of steels machined in different processes are given in Table 1 and Fig. 1. Note that the unit power consumption increases with increasing hardness, which reflects the resistance of the material to the deformation required in machining operations.

Table 1 Average unit power requirements for turning, drilling, and milling plain carbon and alloy steels

Hardness, HRC	Unit power, kW/cm ³ /min (hp/in. ³ /min) ^(a)		
	Turning with a feed of 0.12-0.50 mm/rev (0.005-0.020 in./rev)	Drilling with a feed of 0.05-0.20 mm/rev (0.002-0.008 in./rev)	Milling with a feed of 0.12-0.30 mm/tooth (0.005-0.012 in./tooth)
85-200 HB	0.050-0.064 (1.1-1.4)	0.046-0.059 (1.0-1.3)	0.050-0.064 (1.1-1.4)
35-40	0.064-0.077 (1.4-1.7)	0.064-0.077 (1.4-1.7)	0.068-0.086 (1.5-1.9)

40-50	0.068-0.086 (1.5-1.9)	0.077-0.096 (1.7-2.1)	0.082-0.100 (1.8-2.2)
50-55	0.091-0.114 (2.0-2.5)	0.096-0.118 (2.1-2.6)	0.096-0.118 (2.1-2.6)
55-58	0.155-0.191 (3.4-4.2)	0.118-0.146 (2.6-3.2)	0.118-0.146 (2.6-3.2)

Source: Ref 4

(a) Power requirements at spindle-drive motor, corrected for 80% spindle-drive efficiency.

Fig. 1 Unit power consumption for surface broaching (HSS tools)

The ranges of values for unit power requirements for a particular hardness level cover the spread for sharp and dull tools. The energy is used in deforming metal in the chips and the surface layers of the workpiece and in overcoming friction. Figure 1 shows that decreasing the amount of metal removed by each tooth on a broach increases the unit power consumption, because the friction between the tool and chip or workpiece increases. The same effects occur when feeds are reduced in turning or milling operations. The choice of cutting tool shape and material and the application of coolants have comparatively little effect on the unit power consumption, except by altering the amount of power expended in friction. Unit power consumption cannot be easily correlated with tool life; the factors that affect the unit power consumption are primarily the inherent machinability of the material and the power consumed by friction, while the additional factors that affect tool life include the shape and material of the tool, the temperature of the interface between the tool and chip, and the extent of the abrasive action of the chip on the surface of the tool.

Quality of surface finish is another means of assessing the machinability of materials. Because the surface finish of a machined part may affect its performance in service, it is sometimes useful to rate the machining characteristics of candidate materials in terms of the surface finish that can be expected from machining under specified conditions. Such ratings are generally qualitative, although materials that have high machinability ratings, as determined by other rating methods, usually produce smooth surfaces, partly because they are machined at high speeds.

Machinability Testing for Screw Machines. Although the principles described have been used for judging the machining characteristics of steels by short-time tests made on small amounts of material and for quantifying various characteristics, they are not useful for setting up screw machines. Therefore, engineers concerned with parts produced on automatic bar machines or with making steels for such applications have developed special procedures for determining machinability (Ref 5). Test parts are produced by simultaneous cutting with form tools and by finish-forming and cutoff operations. The conditions to be used and the records to be kept are described in ASTM E 618. Ratings for different lots are assigned on the basis of maximum production rates for parts meeting specified dimensional and surface roughness tolerances.

Scatter in Machinability Ratings

Considerable scatter in the machinability data for the steel chosen as the reference for machinability ratings, B1112, is illustrated in Fig. 2. Within the composition range permitted for that grade, it was found that unintentional variations in carbon, sulfur, and, principally, silicon contents cause the machinability index of B1112 to vary as much as 20% below or 60% above the nominal value of 100 assigned to it. The data on multiple heats of B1113 indicate a similarly large spread of values for that steel.

Fig. 2 Distribution of machinability ratings for B1112 and B1113 steels. Source: Ref 6

The effects of small variations in composition and grain size on machinability are sometimes greater than those from variations in hardness. Therefore, variations in performance should be expected when machining different lots of ostensibly similar material. The scatter in machinability data indicates that the precision of machinability ratings is limited, to some extent at least, by the concept of using the average behavior of a particular grade of steel as the standard for comparison.

In general, differences of 5% in machinability ratings are not likely to be significant or reproducible. It has been shown that such a scatter can result from variations in composition that meet the chemical ranges permitted by specifications for the grade (Ref 7).

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Machinability Ratings of Steels

It is generally agreed that machinability, as defined by tool life, depends on or correlates with the following characteristics of the workpiece:

- Structure
- Chemical composition
- Dispersion of second-phase particles
- Mechanical properties, such as strength and hardness
- Physical properties, such as thermal conductivity

Variations in these characteristics control the performance of workpieces machined under comparable conditions. Materials with superior machinability give better tool lives at equal cutting speeds or permit higher cutting speeds while maintaining equal tool lives. Adopting either alternative--that is, better tool lives or higher cutting speeds--improves productivity and lowers machining costs.

Most published machinability ratings have been based on the performance of steels in one type of operation (usually turning) and with one type of cutting tool. This is particularly true of data from laboratory tests. Consequently, it is of interest to determine whether data obtained with carbide or coated-carbide tools rank materials in the same order of machinability as ratings obtained with HSS tools. Similarly, it is important to determine whether steels exhibiting superiority in one type of operation, such as turning, will also perform better in drilling, boring, milling, or other operations.

In the following two sections, machinability rankings are compared for different cutting tool materials and different machining operations. In both sections, machinability is assessed in terms of cutting speeds. Assuming that the other machining parameters are comparable, the machinability of a material is reflected by its permissible cutting speed for a usefully long tool life. This provides an approach for determining the information mentioned above. Information on suitable cutting speeds, based on experience in many industrial shops, has been collected, evaluated, and published (Ref 1). Usually, the recommended cutting speed gave tool lives of about 2 h for HSS tools and about 1 h for carbide tools.

Order of Machinability Rankings With Different Cutting Tool Materials. The cutting speeds used for the cross plots in Fig. 3 are those recommended for turning metals, at cut depths of 1.0 mm (0.04 in.) and at appropriate feeds, with three types of cutting tools. The workpiece materials represented in Fig. 3 include 3 types of stainless steel, 14 grades of constructional steel, and 5 varieties of cast iron. Their hardnesses ranged from 100 to 325 HB. The plots show close and consistent relationships among the turning speeds recommended for the three types of cutting tools.

HSS		Indexable carbide		Coated carbide

Fig. 3 Correlation among suggested cutting speeds for turning different ferrous metals with indexable-carbide, coated-carbide, and HSS tools. Cutting speeds are from Ref 1.

Table 2 lists the statistical attributes conventionally employed for judging the reliability of the correlations shown in Fig. 3. The goodness of fit between the points and the trend lines is indicated by the correlation coefficient or r value. For the two plots in Fig. 3, the r values are high enough to permit the conclusion that the relationships shown in the chart are statistically significant at the 99.9% level. The coefficients of determination (r^2 values) indicate the proportion of the total variation in the dependent variable explained by its relationship with the independent variable. High proportions of the variance among permissible cutting speeds (89 and 76%) were accounted for by the relationships between indexable carbides and the other two types of cutting tools. The coefficient of determination for the relationship between suggested cutting speeds for coated carbide and steel tools was smaller and less indicative of a strong correlation. The slope and intercept values in Table 2 describe the mean-square trend lines for the relationships when used in an equation with the form:

$$y = (\text{slope})x + (\text{intercept})$$

Table 2 Correlation data of recommended cutting speeds for turning operations with different types of cutting tool materials

The cutting speeds used for these correlation analyses are given in Fig. 3 and are those recommended in Ref 1 for turning 5 types of cast irons, 3 types of stainless steels, and 14 constructional steels.

Paired tool materials		Correlation statistic			
Dependent variable	Independent variable	Correlation coefficient	Coefficient of determination	Slope of trend line (Fig. 3)	Intercept on y-axis (Fig. 3)
HSS	Indexable carbide	0.8722	0.761	0.35	-34.9
Coated carbide	Indexable carbide	0.9427	0.890	1.41	-3.97
HSS	Coated carbide	0.8387	0.703	3.74	241

The correlation data confirm the opinion that workpiece characteristics that improve the ease of machining a metal will be effective in turning tests made with different types of cutting tools. The trend lines also indicate that changing to a better tool material does not raise the permissible cutting speed an equal or fixed amount for different metals.

Order of Machinability Rankings With Different Machining Operations. The cutting speeds prescribed for the same 22 types of ferrous metals were also used to obtain their machinability ratings in different types of operations. The ratings were based on the speeds (in surface feet per minute) recommended for machining with HSS tools (Ref 1). The cutting speeds suggested for 1212 steel, at a hardness level of 150 to 200 HB, were used as the basis for comparison. The machinability rating of a material was taken to be 100 times the ratio of its recommended cutting speed to that for 1212 steel for otherwise comparable cutting conditions.

Figure 4 shows a crossplot of the machinability ratings calculated as above for boring and for turning with a cut depth of 1.0 mm (0.04 in.). The correlation chart shows that the agreement was very close between the two types of metal removal operations. Although not shown in the chart, the least-squares trend lines for machinability ratings based on rough reaming and those based on turning at a heavier cut depth (0.38 mm, or 0.15 in.) closely matched the one shown for boring; that is, they fell within the scatter band of points shown for boring.

Turning	Boring	Turning	Boring
95	94	62	56
100	100	57	56
148	141	53	44
90	88	88	85
162	159	57	65
167	165	95	94
68	65	67	65
58	53	90	88
45	41	71	71
35	32	45	44
68	68	74	74

Fig. 4 Correlations among machinability ratings for different materials based on recommended speeds for turning and for boring with HSS tools. See text for details.

Table 3 gives the correlation statistics comparing the machinability ratings calculated from speeds recommended for different types of operations. Ratings for the first three operations listed in Table 3 were closely related to those based on light turning cuts. They all had very high coefficients of correlation and determination, and the slopes and intercepts for the mean-square trend lines were similar. The correlation coefficients were similar for end milling and for face milling with turning. Nevertheless, they show that the data fit the trend lines quite well. The coefficients of determination indicate that over 73% of the variances were accounted for. On the other hand, the correlation between machinability ratings for drilling and turning was poor when the 22 types of materials were considered in the statistical analysis. Discrepancies of this type are often caused by differences in the ease with which chips can be removed from the scene of the action. In this case, excluding the data for the five cast irons from consideration resulted in a more meaningful correlation, as indicated in the last line in Table 3.

Table 3 Correlation data for the machinability ratings of different machining operations on ferrous materials

Correlation data are based on the machinability ratings^(a) of 22 different types of ferrous materials.

Machining operation compared with turning at 1.0 mm (0.04 in.) depth of cut	Correlation statistic of the machinability ratings ^(a) for the machining operation in the left column and turning with a 1.0 mm (0.04 in.) depth of cut			
	Correlation coefficient	Coefficient of determination	Trend line	
			Slope	Intercept
Turning with a 3.8 mm (0.15 in.) depth of cut	0.9954	0.991	1.02	-2.26
Boring	0.9964	0.993	0.99	-1.13
Reaming	0.9681	0.973	1.08	-10.4
Face milling	0.8827	0.779	0.78	14.9
End milling	0.8583	0.737	0.67	22.5
Drilling ^(a)	0.6786	0.460	0.61	42.7
Drilling^(b)	0.8623	0.740	0.56	37.5

(a) The ratings were calculated from speeds recommended in Ref 1 for machining 22 different types of material with HSS tools. Those speeds were compared with the recommendations for 1212 steel to be processed under similar conditions. The recommended cutting speed for 1212 steel, at 175 HB, was assigned a machinability rating of 100.

(b) Ratings from 17 pairs of observations; ratings for cast iron not considered

Venkatesh and Narayanan (Ref 8) used statistical methods to evaluate relationships among machinability ratings determined by drilling, turning, and milling processes. They found better correlations among ratings from different processes than among those determined with different tool materials.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Microstructure

In general terms, it is possible to differentiate between extremes of metallurgical structure that are easy or difficult to machine. However, when specific cases are encountered, such as differentiating between the machining characteristics of 5130 and 8630 in a particular operation, the presence of a certain microstructure is not, of itself, definitive for selecting one or the other of the two similar steels. This is particularly true when both steels can be heat treated to develop the same type of microstructure.

There are rough correlations among hardness, microstructure, and machinability. Experience teaches that, when machining high- or medium-carbon alloy steels such as 4140, the maximum tool life is obtained with workpieces in the annealed condition. Tool wear is accelerated by increases in hardness level. Based on many observations, machinability theory and practice indicate that the optimum conditions or microstructures for machining steels of different carbon contents are usually as follows:

Carbon, %	Optimum microstructure
0.06-0.20	As-rolled (most economical)
0.20-0.30	Less than 75 mm (3 in.) in diameter, normalized; 75 mm (3 in.) in diameter and over, as-rolled
0.30-0.40	Annealed to give coarse pearlite, minimum ferrite
0.40-0.60	Coarse lamellar pearlite to coarse spheroidite
0.60-1.00	100% spheroidite, coarse to fine

The above examples have only qualitative utility. An attempt to define the relative machinability of steels by a quantitative measure of microstructure has one additional disadvantage: Even assuming that an optimum structural combination could be predetermined and accurately measured, it would still be necessary to regularly achieve this desired

combination on a production basis. This means that all parts would have to be heat treated accurately enough to produce an identical amount and type of microstructure in each. Using commercial steels and production heat treatment practices, such precision is usually impracticable.

Among normalized and annealed steels, those with lower hardness and smaller amounts of pearlite can be machined at higher speeds for equal tool lives. By assuming a direct relationship between carbon and pearlite contents. Kronenberg reported that the life of carbide cutting tools decreased as the carbon content of workpiece steels increased (Fig. 5). Araki and associates (Ref 9) made a similar analysis on data they obtained on 4135 steel that was heat treated to a variety of structures having different hardnesses. As illustrated in Fig. 6, the harder specimens caused tool failure in a shorter time than the softer specimens. These results are comparable to those reported by Armarego and Brown, shown in Fig. 7. An equation of the form:

$$V_c H^x = C \quad (\text{Eq 5})$$

where H is the Brinell hardness number and x and C are empirical constants, has been used by several investigators. Mayer and Lee (Ref 11) combined Eq 1 and 5 to obtain a relationship between relative tool life and hardness for different steels and tool materials, shown in Fig. 8.

Fig. 5 Effect of carbon and pearlite content on cutting speed. Cutting speed for 60-min tool life in steels containing different amounts of carbon and pearlite; 0.65 mm^2 (0.001 in.^2) cross-sectional cutting area; carbide tool

The microconstituents frequently encountered in steels can be identified as contributing to or detracting from the machinability of the steel. Ferrite can be readily cut and causes little tool wear, but it also contributes to the formation of a built-up edge on the tool and a relatively poor surface finish on the workpiece. Spheroidized structures can behave similarly, but large quantities of massive carbide particles can cause significant wear on the tool. Pearlite is harder than ferrite and generally causes greater tool wear; the finer the pearlite plate spacing, the shorter the tool life. A built-up edge is less common when machining pearlite than when machining ferrite. Hard constituents, such as massive carbides or oxides, can be very abrasive to the cutting tool; such particles generally accelerate tool wear. Soft constituents, such as lead or manganese sulfide, generally improve the machinability of the steel.

As discussed above, there are correlations between machinability and several interrelated factors, such as composition, microstructure, and hardness; however, it is not clear that there is an exact causal relationship between any one of these factors and machinability. Furthermore, the effects on machining behavior of these factors acting together are generally less than those from differences in tool materials, tool configurations, or the choice of machining process.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Carbon Steels

Carbon steels nearly always have better machinability than alloy steels of comparable carbon content and hardness. Steels hardened and tempered to hardness levels greater than 300 HB are an exception to this observation; under such conditions, alloy steels have superior machinability, which is usually attributed to, first, the higher tempering temperature required to temper an alloy steel to a specified hardness level and, second, nonuniformity of microstructure due to limited hardenability in carbon steels.

Relative machinability ratings for some plain carbon steels are given in Table 4. Carbon content has a dominant effect on the machinability of carbon steels, chiefly because it governs strength, hardness, and ductility. Increasing the carbon content of steel increases its strength and the unit power consumption for cutting. Data in Fig. 9 show the effects of increasing carbon content and manganese content on unit power consumption.

Table 4 Machinability ratings of plain carbon steels

Machinability ratings are from the percentage of cutting speed for 1212 steel at a given tool life.

SAE/AISI grade ^(a)	Machinability rating	Hardness, HB
1212	100	175
1005	45	95

(a) Values are for steels cold drawn from the hot-rolled condition, unless otherwise indicated.

(b) Annealed, then cold drawn.

(c) Spheroidized, then cold drawn

Fig. 9 Effect of carbon content on unit power consumption. Unit power consumption for hot-rolled and cold-drawn steels of two different manganese levels containing various amounts of carbon

Low-carbon steels containing less than 0.15% C are low in strength in the annealed condition; they machine poorly because they are soft and gummy and adhere to the cutting tools. The machinability of these grades can best be improved by work hardening to raise the strength level and lower the ductility.

Steels in the 0.15 to 0.03% C range are usually machined satisfactorily in the as-rolled, as-forged, annealed, or normalized condition with a predominantly pearlitic structure. The medium-carbon grades, containing up to about 0.55% C, machine best if an annealing treatment that produces a mixture of lamellar pearlite and spheroidite is utilized. If the structure is not partially spheroidized, the strength and hardness may be too high for optimum machinability. For steels with carbon content higher than about 0.55%, a completely spheroidized structure is preferred. Hardened and tempered structures are generally not desired for machining.

Selection of a carbon steel grade within the standard 10xx series is seldom based entirely on machinability, although it may be a factor in selection when other functional requirements can be satisfied by more than one grade. Both tool life and production rate are adversely affected by increases in carbon content. To minimize tool wear and maximize production rate, carbon content should be held to the lowest level consistent with mechanical property requirements.

Carbon content also affects surface finish in machining, although its effect can be greatly modified by the nature of the cutting operation or by the cutting conditions. Low values of surface roughness resulting from machining can be most easily achieved with carbon steels containing approximately 0.25 to 0.35% C.

The practical significance of carbon content to economy in machining is relatively slight in most selection problems involving hardenable carbon steels because the difference in carbon content between steels with equivalent mechanical properties is unlikely to exceed 0.10%. Therefore, assuming a need for comparable mechanical properties, a choice between 1045 and 1050 would be realistic, while a choice between 1030 and 1090 would not.

Machinability of Steels

Resulfurized Carbon Steels

There is a significant improvement in machinability when a resulfurized carbon steel is substituted for a plain carbon steel of approximately the same carbon content. In carbon steels, the sulfur content is ordinarily restricted to a maximum of

0.05%. In the manufacture of resulfurized steels, sulfur is deliberately added to achieve the desired sulfur level. The most common range of sulfur content in resulfurized steels is 0.08 to 0.13%, but some grades permit sulfur content as high as 0.35%. Machinability ratings for standard resulfurized steels are given in Table 5.

Table 5 Machinability ratings of resulfurized and rephosphorized carbon steels, percent of cutting speed for B1112/1212

Grade^(a)	Machinability rating, %	Hardness, HB
1117	90	137

- (d) Proprietary free-machining variants of 12L14 containing bismuth, selenium, or tellurium

Sulfur is added to steel for the sole purpose of decreasing machining costs, either by increasing productivity through greater machining speeds and improved tool life or by eliminating secondary operations through an improvement in finish. Sulfide inclusions, depending on their size, shape, and orientation, improve machining by causing the formation of a broken chip instead of a stringy or continuous chip and by providing a built-in lubricant that prevents the chips from sticking to the tool and undermining the cutting edge. By minimizing this adherence, less power is required, finish is improved, and the speed of machining can often be doubled, compared with machining a similar, nonresulfurized grade. A tightly curled chip that breaks readily is also particularly helpful in milling, deep drilling, tapping, slotting, and reaming because the chip is forced to move within a confined area in these operations.

The reduced friction, lower specific power requirements, and improved chip characteristics when machining resulfurized steels all contribute to increased production rates. The advantage of free-machining steels over carbon and alloy grades in terms of unit power consumption is shown in Fig. 10. The difference is important because almost all the energy of cutting is converted into heat in the cutting zone.

Fig. 10 Unit power consumption for free-machining and standard grades of carbon and alloy steels as a function of hardness

The manganese content of resulfurized steels must be high enough to ensure that all the sulfur is present in the form of manganese sulfide (MnS) particles. When a high sulfur content is accompanied by an increase in manganese content, a better surface finish is obtainable, which usually results in an improvement in dimensional accuracy.

Control and Effect of Sulfide Morphology. The control of MnS particle shape, size, and distribution is a critical aspect of steelmaking (Ref 12). The particles may remain somewhat globular or may become elongated during rolling to form stringers parallel to the direction of rolling. Figure 11 shows that the size and shape of sulfide particles have pronounced effects on the machinability of steels having similar compositions. The two bars came from different ingots in the same heat. In this case, the difference in machinability was caused by variations in oxygen content and was reflected by the differences in silicon content. The presence of aluminum or other strong deoxidizers changes the shape of sulfide

inclusions and may impair machinability. In theory at least, differences in rolling practice that affect the characteristics of sulfide inclusions also influence machinability.

Chemical composition, %	Steel A	Steel B
Carbon	0.07	0.07
Manganese	0.94	0.94
Sulfur	0.200	0.200
Phosphorus	0.094	0.093
Silicon	0.009	0.044
Machinability rating, %	176	125

Fig. 11 Influence of size and shape of sulfide inclusions on machinability. Two steels, identical in composition except for silicon content, exhibited different machinability ratings that were traced to differences in the size and shape of MnS inclusions. Source: Ref 12

For years, the beneficial effects of large, globular sulfides on machinability have been realized by controlling the silicon contents of semikilled steels (Ref 12). Recently, the effects of inclusion morphology on other characteristics have received considerable attention. Striking benefits resulting from changing inclusions have been reported, but there has been less agreement about the mechanisms through which they act.

Royer (Ref 13) reported that a 25% improvement in machinability resulted from increasing the manganese content of type 303 stainless steel. He attributed the improvement to softer, less abrasive sulfide inclusions. Presumably, the higher manganese level may also have affected the total volume and size of the manganese sulfides.

Yaguchi (Ref 14) measured thrust and cutting forces in tests on leaded, free-cutting steels. The life to catastrophic failure of the HSS tools improved considerably with inclusion size. The minima in cutting forces shifted toward higher speeds as

the sulfides increased in size. Yaguchi concluded that the size of the inclusions influenced the temperature distribution at the tip of the tool and indirectly affected the formation of the built-up edge on the tool. It is widely known that the presence or absence of a built-up edge influences tool life.

Abeyama and associates (Ref 15) controlled the morphology of sulfides in resulfurized free-cutting steels through additions of tellurium. Treatments producing Te/S ratios of 0.2 were most effective in improving machinability, and these treatments also reduced the anisotropy of mechanical properties. The researchers attributed both effects to the influence of tellurium on the melting or softening temperatures of the inclusions. Raising the melting point of the sulfides by alloying would minimize the elongation of the mixed sulfides during hot rolling.

Katayama (Ref 16) found that sulfide shape also affected the machinability of continuously cast billets. This subject is of interest because steels made by that practice, rather than from ingots, have smaller as-cast inclusions that are not elongated as much during hot rolling because the reductions are smaller. However, this difference between ingots and continuously cast steel may not always manifest itself in terms of machinability. Welburn and Naylor (Ref 17) reported that the machinability of 1144 steel made from continuously cast billets is equivalent to that of bars made from ingots. Their conclusions were based on both laboratory tests and experience by customers.

Economic factors influence the use of resulfurized steels because resulfurized grades cost more than plain carbon steels. For example, 25 mm (1 in.) round hot-rolled bars of 1117 steel cost approximately 8% more than plain carbon steel bars of a composition that is similar except for the sulfur content. Nevertheless, the economic benefits of machining resulfurized steels are large enough to justify annual purchases of 2 million tons of free-cutting steel in the United States.

The use of resulfurized grades depends on whether the higher steel cost can be offset by lower machining cost. Considering only the cost of removing chips, the use of free-cutting steels can seldom be justified if less than about 10% of the bar is removed in machining the parts. However, as the amount of metal machined off approaches or exceeds 20%, the resulfurized grades should be considered. When the required finish can be obtained in a primary operation with a free-cutting grade but a secondary operation would be necessary for a grade that is not free cutting, the 11xx series can be justified for a smaller amount of metal removal. In such parts, the savings in handling and the elimination of an operation usually more than offset the extra cost of the steel without consideration of machining speed or tool life.

Figure 12 illustrates how the substitution of heavily drawn and stress-relieved 1144 for heat-treated 1046 can significantly increase the number of parts machined between regrinds of the tools and therefore the cost of manufacturing the part.

Fig. 12 Comparison between machining 1046 and 1144

Carbon Steels With Other Additives

Phosphorus, as well as sulfur, is often added to improve the machining characteristics of low-carbon steels. The phosphorus range for 12L14 and 1215 is 0.04 to 0.09%. The phosphorus limits are 0.07 to 0.12% for other steels in the 12xx series. The limits are set because phosphorus, like carbon, increases the hardness and strength of the steel. Consequently, excessive phosphorus contents impair machining characteristics and some other properties of steel.

Phosphorus is soluble in iron and increases the strength of ferrite, an effect that promotes chip breaking in cutting operations. The phosphorus helps to avoid the formation of long, stringy chips in some operations and may result in a better surface finish.

Nitrogen. The effects of nitrogen on the machining characteristics of 12L14 steel were studied by Watson and Davies (Ref 18). They found that nitrogen adversely affected the life of HSS tools used for turning and form cutting. This effect was attributed to strain age hardening, caused by nitrogen, before testing. No beneficial effects of nitrogen were detected.

Selenium and tellurium additions improve machinability but are not available in standard grades of steel. These additions are expensive (selenium treatment increases the cost of steel by about 15%). When they are used, they are often used in combination with sulfur or lead. Typical percentages of either element would be 0.04 or 0.05%. Both elements seem to exert beneficial effects by promoting the retention of globular-shaped sulfide-type inclusions. For the same reason, they are considered to have a less deleterious effect than sulfur on mechanical properties. The data in Fig. 13 show that the effect of tellurium on machinability can be appreciable. The data were obtained on steels with a nominal tensile strength of 1035 MPa (150 ksi) by turning with a form tool and measuring the diameters of successive parts. The presence of 0.042% Te quadrupled the number of parts made between tool changes and improved the surface finish. Tata and Sampsell (Ref 19) reported that selenium is even more effective than tellurium in improving the machinability of steels, particularly alloy steels.

Fig. 13 Effect of tellurium on tool wear. Tool wear, as measured by part growth, in multiple-operation machined parts of quenched and tempered 4142 and a similar grade with tellurium. Cutting speed was 0.5 m/s (99 sfm). Source: Ref 11

Calcium additions improve the machining characteristics of steels fully deoxidized with aluminum. The cost of the special treatment is relatively modest. Steels made by aluminum deoxidation practices ordinarily contain small inclusions of aluminum silicate in quantities essentially independent of the amount of aluminum added to the steel. The inclusions are often assumed to be alumina, and the poorer machinability of aluminum-killed steels, compared to steels deoxidized with silicon, is often attributed to the supposedly abrasive effects of the inclusions. The validity of this explanation is debatable. Calcium additions result in larger inclusions consisting of calcium-aluminum silicates. Joseph and Tipnis (Ref 20) considered these inclusions to be softer and less abrasive than those in steels not treated with calcium and concluded that such attributes benefited machinability. Tests on a series of 1045 steels led Subramanian and Kay (Ref 21) to the same conclusions.

Abeyama and colleagues (Ref 15, 22) demonstrated that calcium treatments benefit the machining characteristics of several types of steel. Their studies on heavy-duty steels led them to believe that machinability is affected by the chemical composition of the inclusions and by temperatures at the tool point. Fombarlet (Ref 23) attributed the better machining properties of 1048, 4142, and 8620 steels to appropriate treatments with calcium.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Leaded Carbon and Resulfurized Steels

The addition of lead to carbon steels is another means of increasing the machinability of the steels and improving the surface finish of machined parts. Lead is added to the molten steel during teeming of ingots or, sometimes, to the ladle. Because lead is insoluble, or nearly so, in molten steel, a fine dispersion of lead particles develops as the steel solidifies. The lead is usually found near or surrounding the sulfide inclusions. On special order, nearly all carbon steels in the 10xx and 11xx series can be produced with 0.15 to 0.35% Pb. The grades are identified by inserting the letter "L" between the second and third numerals of the grade designation, for example, 10L45. It is generally believed that lead has a minimal effect on the yield or ultimate strength, ductility, or fatigue properties of steels at room temperature and moderate strength levels. Lead can also be added to alloy steels to improve machinability without sacrificing room-temperature mechanical properties. Environmental considerations may restrict the manufacture or use of leaded steels.

Leaded steels cost about 5% more than similar nonleaded compositions. Because requirements of machinability and finish are the only reasons for using leaded grades, the extra cost for these steels must be justified by either or both of these factors.

As with resulfurized grades of carbon steel, consideration must be given to the amount of stock being removed. For example, if only 10% of the bar weight is to be removed in machining, the extra cost for leaded grades may not be justifiable. However, if 20% or more of the bar is converted to chips, the leaded grades should be considered.

The problem of surface finish requires consideration of specific parts, and no general statements are valid. In a case study of one particular part, the finish obtained in drilling and reaming standard 1050 steel was marginal, and parts were frequently rejected and subsequently reworked. The use of leaded 1050 corrected this condition, and the added cost of the steel was justified by finish alone.

Most of the resulfurized grades can be produced with an addition of 0.15 to 0.35% Pb. The lead addition augments the effect of sulfur, permitting a further increase of machining speed and better finish. For screw machine parts where more than 50% of the bars become chips, there may be justification for the higher cost, especially where there are high finish requirements.

The increased cost of leaded steel is unjustified when machine tools are already being operated at maximum speed on plain resulfurized steels. On the other hand, machine tools that have been designed for higher speeds can take advantage of the leaded resulfurized grades.

In another case study, surface finish was the deciding factor in selecting a leaded steel for parts about 13 mm ($\frac{1}{2}$ in.) in diameter and 75 mm (3 in.) long made from 1141 steel on a multiple-operation machine. Finish requirements on the ends of the parts could not be met in the cutoff operation, and a secondary facing operation was necessary. A change to leaded 1141 steel provided just enough better finish from the cutoff operation so that the finish requirement could be met, and the elimination of the facing operation justified the cost of the leaded grade.

The example shown in Fig. 14 illustrates the importance of machinability of steel in determining the cost of small parts. A change from 1213 to 12L13 nearly doubled the production rate of these bushings and reduced the total cost per part, even though the 12L13 steel was more costly.

Fig. 14 Effect of lead content on multiple-operation machining. Graphs show the production rate and relative cost of machining bushings from 1113 and 12L13 steel with cutting speeds chosen for an 8-h tool life.

Reh and coworkers (Ref 24) described the characteristics of lead-free, high-sulfur steels containing bismuth. They found bismuth to be more efficient than lead in reducing cutting forces and in improving surface finish. They attributed the pronounced improvements caused by bismuth to the spheroidization of inclusions and to the liquid-metal embrittlement of grain boundaries, by liquid bismuth, during cutting.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Carburizing Steels

It is difficult to evaluate the relative machining economy of plain carbon carburizing steels, except in terms of specific parts, largely because these steels possess conflicting properties that may either promote or detract from economy in machining. On the one hand, their low carbon content may be beneficial to tool life and production rate. However, their relatively soft, gummy structure results in a tearing action in cutting, which is harmful to surface finish and dimensional accuracy. It is this conflict in properties that sometimes makes it advantageous to machine or partially machine these steels in the carburized condition. Although higher carbon content adversely affects tool life, the higher carbon areas are more controllable in terms of surface finish and dimensional accuracy. In operations such as gear cutting, the finish and accuracy may be more decisive factors than tool wear or production rate.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Through-Hardening Alloy Steels

The steels chosen for parts that must be hardened throughout must contain enough carbon to achieve the desired hardness after quenching and sufficient alloy content to obtain the desired percentage martensite in the thickest section of the part. The combination of carbon and alloy contents can make these steels difficult to machine. The extent of the difficulties encountered in machining these steels depends primarily on the microstructure and hardness of the steel and secondarily on its alloy content. Figure 15 illustrates the magnitude of the variations in tool life that may be expected from differences in hardness and microstructure in a single steel, 4340. A similar effect for 4135 steel is shown in Fig. 6. Machinability ratings for several alloy steels are given in Table 6.

Table 6 Machinability ratings for alloy steels compared to 1212 steel

The machinability rating of 1212 steel is assigned at 100.

Fig. 15 Effect of hardness on tool life curves. Workpiece: 4340 steel. Tool material: C6 carbide. Source: Ref 25

A comparison of the machinability ratings with the compositions of these steels indicates that all of the alloying elements that increase the hardenability of the steel decrease machinability; ferrite-strengthening elements such as nickel and silicon decrease the machinability more than equivalent amounts of carbide-forming elements such as chromium and molybdenum.

It is not uncommon for heat-treating considerations to overshadow both machining and material costs in the selection of steel. On occasion, heat-treating responses may dictate the selection of a less machinable or a more expensive steel so that the lowest total costs can be realized.

The sulfur content of through-hardening alloy steels can significantly affect machining behavior. Variations in residual sulfur level can account for unexplained differences in the machining behavior of different lots of the same material. Many grades of hardenable alloy steels can be obtained in the resulfurized condition. The differences in tool life and cutting speed between standard and high-sulfur 4150 steels are substantial. Tests by Field and Zlatin (Ref 26) showed that raising the sulfur content from 0.04 to 0.09% increased the cutting speed for 60-min tool life by 25%. Alloy steels containing lead are available and useful. As indicated in Table 6, the machinability rating of the leaded grade 41L40 is 85, while the rating for 4140 is only 65. The performance of these two grades in several machining operations is indicated in Table 7. The data are from a case study described in Ref 26.

Table 7 Effect of lead on cutting speed and tool life in machining alloy steels

Operation	Standard 4140	Leaded 4140
Turning		
Hardness, HB	300	300
Cutting speed, rev/min	321	495

Feed, mm/rev (in./rev)	0.30	0.30
	(0.012)	(0.012)
Tool life, parts per tool grind	4	18-20
Turning		
Cutting speed, rev/min	460	740
Feed, mm/rev (in./rev)	0.15	0.23
	(0.006)	(0.009)
Drilling ^(a)		
Cutting speed, m/min (sfm)	8.76	10.55
	(28.75)	(34.6)
Feed, mm/rev (in./rev)	0.10	0.15
	(0.004)	(0.006)

- (a) In drilling standard 4140 steel, the 19 mm ($\frac{3}{4}$ in.) diam hole jammed with chips and the drill had to be removed frequently for cleaning. When using leaded 4140 steel, the entire depth was drilled without removing the tool.

Another important factor that can affect the choice of steel for a through-hardening application is the effect of alloying elements added for machinability on the mechanical properties of the steel. These steels are often used at high-strength levels, where the deleterious effects of inclusions, particularly on transverse properties, might not be permissible. The effect of sulfur, in the amounts usually specified for enhanced machinability, is generally considered to be more damaging than that of lead. For some applications, neither machinability additive can be tolerated.

Machinability of Steels

Francis W. Boulger, Battelle-Columbus Laboratories (retired)

Cold-Drawn Steel

Cold drawing generally improves the machinability of steels containing less than about 0.2% C. The improvement is most noticeable in plain carbon steels, as shown in Fig. 16. The machinability of higher-carbon steels, or alloy steels, is less affected by cold work. This improvement in machinability may be attributed to reduced cutting forces and/or the characteristics of chip removal. Kopalinsky and Oxley (Ref 28) found that cold drawing lowered the cutting forces and improved the tool life and surface finish of low-carbon steels. Screw machine tests by Yaguchi (Ref 29) showed that the workpiece surface finish improved continuously with increases in reduction in area up to 29%. These effects were not characteristic of steels with high nitrogen contents (Ref 18). The improved machinability of cold-drawn steels can also be attributed to the decrease in ductility that results from cold working; thus, the chips are generally not long and stringy.

Fig. 16 Effect of cold drawing on tool life. Workpiece: 1016 steel, 25 mm (1 in.) in diameter. Machining conditions: multiple-operation machined with a cutting speed of 0.73 m/s (144 sfm). Source: Ref 27

Cold-finished bars have closer dimensional tolerances, better surfaces, and usually, higher strength than hot-finished bars. The first two factors may be significant in the selection of steels to be machined in multiple-operation machines or other high-production equipment. These considerations are discussed in the article "Cold-Finished Steel Bars" in this Volume.

The machining characteristics of cold-drawn steels are only rarely a decisive criterion for selection. The extra strength obtained with cold-drawn steel may be more important from a cost standpoint, because it is often high enough to eliminate the need for heat treatment.

Weldability of Steels

S. Liu, Center for Welding and Joining Research, Colorado School of Mines; J.E. Indacochea, Department of Civil Engineering, Mechanics, and Metallurgy, University of Illinois at Chicago

Introduction

THE MAIN OBJECTIVE of this article is to survey the factors controlling the weldability of carbon and low-alloy steels in arc welding. A good understanding of the chemical and physical phenomena that occur in the weldment is necessary for welding modern steels. Therefore, the influence of operational parameters, thermal cycles, and metallurgical factors on weld metal transformations and the susceptibility to hot and cold cracking are discussed. Common tests to determine steel weldability are also described.

The carbon and low-alloy steels group comprises a large number of steels that differ in chemical composition, strength, heat treatment, corrosion resistance, and weldability. These steels can be further divided into subgroups:

- Carbon steels
- High-strength low-alloy (HSLA) steels
- Quenched and tempered (QT) steels
- Heat-treatable low-alloy (HTLA) steels
- Precoated steels

This article addresses only the basic principles that affect the weldability of carbon and low-alloy steels. More detailed information concerning the other aspects of welding, such as joint design, defects, and failure in weldments and the influence of these factors on different groups of steels, can be found in Volumes 1 and 6 of the 9th Edition *Metals Handbook* and Volume 11 of *ASM Handbook*, formerly 9th Edition *Metals Handbook* and in the "Selected References" at the end of this article.

Weldability of Steels

Characteristic Features of Welds

Single-Pass Weldments. To understand weldability, it is necessary to recognize the various weld regions. In the case of a single-pass bead, the weldment is generally divided into two main regions: the fusion zone, or weld metal, and the heat-affected zone (HAZ), as shown in Fig. 1. Within the fusion zone, the peak temperature exceeds the melting point of the base metal, and the chemical composition of the weld metal will depend on the choice of welding consumables, the base metal dilution ration, and the operating conditions.

Fig. 1 Various regions of a bead-on-plate weld

Under conditions of rapid cooling and solidification in the weld metal, alloying and impurity elements segregate extensively to the center of the interdendritic or intercellular regions and to the center parts of the weld, resulting in significant local chemical inhomogeneities. Accordingly, the transformation behavior of the weld metal may be quite different from that of the base metal, even when the bulk chemical composition is not significantly changed by the welding process. The typical anisotropic nature of the solidified weld and structure is also shown in Fig. 1.

The chemical composition remains largely unchanged in the HAZ because the peak temperature remains below the melting point of the parent plate. Nevertheless, considerable microstructural change takes place within the HAZ during welding as a result of the extremely harsh thermal cycles. The material immediately adjacent to the fusion zone is heated high into the austenitic temperature range. The microalloy precipitates that development in the previous stages of processing will generally dissolve, and unpinning of austenite grain boundaries occurs with substantial growth of the grains, forming the coarse-grain HAZ. The average size of the austenite grains, which is a function of the peak temperature attained, decrease with increasing distance from the fusion zone. The cooling rate also varies from point to point in the HAZ; it increases with increasing peak temperature at constant heat input and decreases with increasing heat input at constant peak temperature. Because of varying thermal conditions as a function of distance from the fusion line, the HAZ is actually composed of coarse-grain zones (CGHAZ), fine-grain zones (FGHAZ), intercritical zones (ICHAZ), and subcritical zones (SCHAZ). The various HAZ regions of a single-pass low-carbon steel butt weld are shown in Fig. 2.

Fig. 2 Various regions of the HAZ of a single-pass low-carbon steel weld metal with 0.15 wt% C

In multipass weldments, the situation is much more complex because of the presence of reheated zones within the fusion zone, as shown in Fig. 3. The partial refinement of the microstructure by subsequent weld passes increases the inhomogeneity of the various regions with respect to microstructure and mechanical properties. Reaustenitization and subcritical heating can have a profound effect on the subsequent structures and properties of the HAZ. Toughness property deterioration is related to small regions of limited ductility and low cleavage resistance within the CGHAZ that are known as the localized brittle zones (LBZ). Localized brittle zones consist of unaltered CGHAZ, intercritically reheated coarse-grain (IRCG) heat-affected zone, and subcritically reheated coarse-grain (SRCG) heat-affected zone. At an adjacent fusion line, that LBZs may be aligned, as shown in Fig. 3. The aligned LBZs offer short and easy paths for crack propagation. Fracture occurs along the fusion line.

Fig. 3 Overlapping of HAZ to form localized brittle zones aligned along the fusion line

Weldability of Steels

Metallurgical Factors That Affect Weldability

Hardenability and Weldability. Hardenability in steels is generally used to indicate austenite stability with alloy additions. However, it has also been used as an indicator of weldability and as a guide for selection a material and welding process to avoid excessive hardness and cracking in the HAZ. Steels with high hardness often contain a high

volume fraction of martensite, which is extremely susceptible to cracking during processing. Hardenability is also used to indicate the susceptibility of a steel to hydrogen-induced cracking.

Traditionally, empirical equations have been developed experimentally to express weldability. Carbon equivalent (CE) is one such expression; it was developed to estimate the cracking susceptibility of a steel during welding and to determine whether the steel needs pre- and postweld heat treatment to avoid cracking. Carbon equivalent equations do include the hardenability effect of the alloying elements by expressing the chemical composition of the steel as a sum of weighted alloy contents. To date, several CE expressions with different coefficients for the alloying elements have been reported. The International Institute of Welding (IIW) carbon equivalent equation is:

$$\text{CE} = \text{C} + \frac{\text{Mn}}{6} + \frac{\text{Ni}}{15} + \frac{\text{Cu}}{15} + \frac{\text{Cr}}{5} + \frac{\text{Mo}}{5} + \frac{\text{V}}{5} \quad (\text{Eq 1})$$

where the concentration of the alloying elements is given in weight percent. It can be seen in Eq 1 that carbon is the element that most affects weldability. Together with other chemical elements, carbon may affect the solidification temperature range, hot tear susceptibility, hardenability, and cold-cracking behavior of a steel weldment. Figure 4 summarizes the CE and weldability description of some steel families. Because of the simplification and generalization involved in Fig. 4, it should be used cautiously for actual welding situations.

Fig. 4 Weldability of several families of steels as a function of carbon equivalent. 1, Mo; 2, Cr + Ni + Mo + Si, and so on; 3, Cr or V or Ni + Si, and so on

The application of CE expressions is also empirical. For example, the IIW carbon equivalent equation has been used successfully with traditional medium-carbon low-alloy steels. Steels with lower CE values generally exhibit good weldability. When the CE of a steel is less than 0.45 wt%, weld cracking is unlikely, and no heat treatment is required. When the CE is between 0.45 and 0.60 wt%, weld cracking is likely, and preheat in the range of approximately 95 to 400 °C, (200 to 750 °F) is generally recommended. When the CE of a steel is greater than 0.60 wt%, there is a high

probability that the weld will crack and that both preheat and postweld heat treatments will be required to obtain a sound weld.

However, Eq 1 does not accurately correlate with the microstructures and properties of newly developed low-carbon microalloyed steels over extended alloy ranges. Thus, new expressions based on solution thermodynamics and kinetic considerations were developed to obtain better predictions of the alloy behavior and weldability of low-carbon low-alloy steels. Complex interactive terms, rather than simple additive forms, are included in these equations. An example of one such expression is:

$$\begin{aligned} \text{CE} = & k_1 C [1 + k_2 C + k_3 \text{Mn} + \dots \\ & + k_{11} \ln C + k_{22} C \ln C + k_{33} \text{Mn} \ln \text{Mn} \\ & + \dots + k_{111} C \text{Mn} + \dots] \end{aligned} \quad (\text{Eq 2})$$

where k_1, k_2, \dots , and so on, are the weighted coefficients multiplied to the concentration of the alloying elements. Nonlinear terms such as $\ln X_i, X_i \ln X_i$, and $X_i X_j$ represent the interaction effect among the alloying elements X_i and X_j . Equations with these nonlinear terms are more useful in predicting arc welding behavior.

Several expressions are also available for other steel groups with a wider range of alloying elements and with different prior heat treatments, hydrogen contents, and weld hardnesses. Recently, expressions that include fabrication conditions such as heat input, cooling rate, joint design and restraint conditions have also been proposed. An example of this type of equation is:

$$P_H = P_{cm} + 0.075 \log_{10} H + \frac{R_f}{40\,000} \quad (\text{Eq 3})$$

where P_H is the cracking susceptibility parameter, H is the concentration of hydrogen (in parts per million), R_f is the restraint stress (in megapascals), and:

$$\begin{aligned} P_{cm} = & C + \frac{\text{Mn}}{20} + \frac{\text{Si}}{30} + \frac{\text{Cu}}{20} + \frac{\text{Ni}}{60} + \frac{\text{Cr}}{20} \\ & + \frac{\text{Mo}}{15} + \frac{\text{V}}{10} + 5B \end{aligned} \quad (\text{Eq 4})$$

The thickness of the part being welded can also be related to CE as a compensated carbon equivalent (CCE) as follows:

$$\text{CCE} = \text{CE} + 0.00254e \quad (\text{Eq 5})$$

where e is the thickness of the part (in millimeters). Equations 3, 4, and 5 are valid only for specific ranges of chemical composition and welding conditions. Nevertheless, despite the different forms and terms included in the predictive equations, the main objective remains that of estimating the weldability and cracking susceptibility of the material.

Weld Metal Microstructure. Inherent in the welding process is the formation of a pool of molten metal directly below a moving heat source. The shape of this molten pool is determined by the flow of both heat and metal, with melting occurring ahead of the heat source and solidification occurring behind it. Heat input determines the volume of molten metal and therefore the dilution and weld metal composition, as well as the thermal conditions under which solidification takes place. Also important to solidification is the crystalline growth rate, which is geometrically related to weld travel speed and weld pool shape. Thus, weld pool shape, weld metal composition, cooling rate, and growth rate are all factors that are interrelated with heat input, which in turn will affect the solidification microstructure and the tolerance of the weldment to hot cracking.

Incipient melting at base metal grain boundaries immediately adjacent to the fusion zone allows these grains to serve as seed crystals for epitaxial grain growth during weld metal solidification. The continuous growth of the epitaxial grains results in large columnar grains whose boundaries provide easy paths for crack propagation. An elongated weld pool will

yield straight and broad columnar grains, which promote the formation of centerline cracking because of impurity segregation, mechanical entrapment of inclusions, and the shrinkage stresses that develop during solidification. Epitaxial columnar growth is particularly deleterious in multipass welds where grains can extend continuously from one weld bead to another.

Hot tears originate near the liquid/solid interface when strains from solidification shrinkage and thermal contraction cause rupture of the liquid films of low melting point located at grain boundaries. The susceptibility of an alloy to hot tearing is related to its inability to accommodate strain through dendrite interlocking as well as the tendency of tears to backfill with the remaining liquid. The time interval during which liquid films can exist in relation to the rate of strain generation may also play a role in hot tear susceptibility. Ferrous alloys can be hot tear sensitive depending on the amount of phosphorus and sulfur impurities they contain. Carbon and nickel are also known to influence hot cracking in steel welding.

When the solidified steel weld metal cools down, solid-state transformation reactions may occur. As in solidification, the two main factors that determine the final microstructure are the chemical composition and thermal cycle of the weld metal. In most structural steels, weld metal will solidify as δ -ferrite. At the peritectic temperature, austenite will form from the reaction between liquid weld metal and δ -ferrite, and subsequent cooling will lead to the formation of α -ferrite. During the austenite-to-ferrite transformation, proeutectoid ferrite forms first along the austenite grain boundaries; this is known as grain-boundary ferrite. Subsequent to grain-boundary ferrite formation, ferrite sideplates develop in the form of long needlelike ferrite laths that protrude from the allotriomorphs. A coarse austenite grain size and a low carbon content, in combination with a relatively high degree of supercooling, are found to promote ferrite sideplate formation. These laths can be properly characterized by their length-to-width aspect ratios; values above 10:1 are common.

As the temperature continues to drop, intragranular acicular ferrite will nucleate and grow in the form of short laths separated by high angle boundaries. The inclination between orientations of adjacent acicular ferrite laths is usually larger than 20° . The random orientation of these laths provides good resistance to crack propagation. Acicular ferrite laths have aspect ratios ranging from 3:1 to 10:1.

During proeutectoid ferrite formation, carbon is rejected continuously from the ferrite phase, enriching the remaining austenite, which later transforms into a variety of constituents, such as martensite (both lath and twinned), bainite, pearlite, and retained austenite. Because of the acicular nature of the bainite laths, they can also be described by their aspect ratio, with values similar to those of Widmanstätten side-plates. More frequently, however, bainite laths occur in the form of packets associated with grain boundaries. Figure 5 illustrates the microstructure of a low-carbon steel weld metal.

Fig. 5 Weld metal microstructure of HSLA steel. A, grain-boundary ferrite; B, acicular ferrite; C, bainite; D, sideplate ferrite

Heat-Affected Zone Microstructure. In terms of microstructure, long bainite laths with alternate layers of connected martensite islands are generally found in the CGHAZ of high-strength low-alloy steel weldments. Martensite islands (martensite-retained austenite constituents) are formed because of the enrichment of carbon in austenite in the intercritical zone. Coarse austenite grain size in the near-fusion region of the HAZ can suppress high-temperature transformation products in favor of martensite and bainite upon cooling. Upper bainite has a relatively high transformation temperature and is stable relative to the thermal cycles subsequent to those of the first pass. Fluctuation of the chemical composition of the microalloying elements could also contribute to carbon equivalent change and to the amount of hard martensite present in the CGHAZ.

In the FGHAZ, even though the peak temperature attained is above thermal cycle Ac_3 , it is still well below the grain-coarsening temperature. The smaller prior-austenite grain size and subsequent ferrite transformation produce a refined microstructure having grains smaller than those of the parent material. The microstructure is similar to that of a normalized steel, with considerable toughness.

Only partial transformation takes place in the ICHAZ, resulting in a mixture of austenite and ferrite at the peak temperature of the thermal cycle. Upon cooling, the austenite in a matrix of soft ferrite decomposes, and the final microstructure depends on the bulk and local composition of the alloying elements. The cooling rate is also an important factor in determining the amount of martensite and bainite in the ferrite matrix. In the SCHAZ, no observable microstructural changes are observed. Some spheroidization of carbides may occur.

Upon reheating by subsequent weld passes, precipitates or preprecipitate clusters may form, reducing the toughness. Irregularly shaped particles may also coalesce and strain the surrounding matrix, further lowering the toughness. During HAZ thermal cycles between Ac_1 and Ac_3 , the austenite becomes enriched with carbon, which, upon cooling, transforms to martensite islands. In the as-welded condition, this transformation affects the IRCG region more than the other reheated zone. Figure 6 illustrates the different phases that can be found in a low-carbon steel HAZ.

Fig. 6 Heat-affected zone exhibiting a wide variety of microstructures in the intercritical and subcritical regions. A, spheroidized carbides; B, bainite and martensite

Chemical Composition Effect. The presence of a certain phase in the final microstructure of a weldment can be explained by means of a continuous cooling transformation (CCT) diagram, which is formed by two sets of curves: the percent transformation curves and the cooling curves. The percent transformation curves define the regions of stability of the different phases. The cooling curves represent the actual thermal conditions that the weld experienced. The intersection of these two sets of curves determines the final microstructure of the different weld zones. Figure 7 illustrates the use of a CCT diagram to determine the microstructure of a low-carbon low-alloy steel weld metal.

Fig. 7 Continuous cooling transformation diagram for an HSLA steel weld metal showing the effect of cooling rate and chemical composition on microstructure. CR, cooling rate

Hardenability elements, such as carbon, manganese, chromium, and molybdenum, suppress the start of austenite decomposition to lower temperatures. This is equivalent to pushing the transformation curves to the right side of the CCT diagram, resulting in a refined microstructure. Inclusion formers, such as oxygen and sulfur, accelerate the austenite-to-ferrite transformation by providing more nucleation sites for the reaction to initiate at higher temperatures.

Faster cooling has the same effect as an increase in hardenability elements, while a slower cooling rate acts in the same direction as a decrease in hardenability agents or an increase in nucleation site providers. Because the cooling rate varies from point to point in the HAZ, the microstructure also changes accordingly, with martensite and bainite in regions close to the fusion line.

Preweld and Postweld Heat Treatments. In the welding of carbon and low-alloy steels, the final microstructure of the weldment is primarily determined by the cooling rate from the peak temperature. Because the alloy level in carbon and low-alloy steel is low, the major physical properties of the steel are not affected. Thus, temperature gradient and heat input become the important parameters in weld metal microstructural evolution. A slower cooling rate decreases shrinkage stress, prevents excessive hardening, and allows time for hydrogen diffusion. Cooling rate (CR) is of particular importance and is a function of the difference in temperature, ΔT , as well as the thermal conductivity of the material, k . The cooling rate can be expressed for thinplate and thick-plate welding, respectively, as:

$$\begin{aligned} CR &\propto k \Delta T^3 \\ CR &\propto k \Delta T^2 \end{aligned} \quad (\text{Eq 6})$$

During preheating, the initial temperature of the plate increases, decreasing the cooling rate and the amount of the hard phases, such as martensite and bainite, in the weld microstructure. For the welding of hardenable steels, it is important to determine the critical cooling rate (CCR) that the base metal can tolerate without cracking:

$$CCR(^{\circ}\text{F/s}) = \frac{6.598}{(CE - 0.3074)} - 16.26 \quad (\text{Eq 7})$$

The higher the carbon equivalent of an alloy, the lower the critical or allowable cooling rate. The use of a low-hydrogen welding electrode also becomes more important. Preheating should be applied to adjust the cooling rate accordingly.

Weldability of Steels

S. Liu, Center for Welding and Joining Research, Colorado School of Mines; J.E. Indacochea, Department of Civil Engineering, Mechanics, and Metallurgy, University of Illinois at Chicago

Weld Cracking

Most evidence indicates that a weld-cracking failure mechanism is microstructure related. In the case of cold cracking, recent crack tip opening displacement (CTOD) results show that the reduction in toughness of HSLA weldments is related to the CGHAZ and that cracks generally propagate along or near the fusion line. The CGHAZ of microalloyed steel welds generally exhibits the highest hardness of the entire HAZ. The high-carbon untempered martensite in this region is the major cause of embrittlement. The amount of precipitates (carbides, nitrides, and carbonitrides) is found to be the highest in the regions next to the SCHAZ and the lowest at or next to the fusion line. As a result, there is a slight increase in microalloying element in solution in the CGHAZ, which increases the hardenability of this region.

Hydrogen-Induced Cracking. The effect of hydrogen on weld cracking should also be mentioned. Moisture pickup from the atmosphere that is incorporated into the molten puddle, either directly or via the welding consumables, is the main source of hydrogen. The presence of hydrogen increases the HAZ cracking susceptibility of high-strength steel weldments. Also known as underbead, cold, or delayed cracking, it is perhaps the most serious and least understood of all weld-cracking problems. It generally occurs at the temperature below approximately 95 °C (200 °F) either immediately upon cooling or after a period of several hours. The crack can be both transgranular and intercrystalline in character, but mainly follows prior-austenite grain boundaries. The initiation of cold cracking is particularly associated with notches, such as the toe of the weld, or with inhomogeneities in microstructure that exhibit sudden changes in hardness, such as slag inclusions, martensite/ferrite interfaces, or even grain boundaries. Like most other crack growth phenomena, hydrogen-induced cracking is accentuated in the presence of high-restraint weld geometries and matrix hardening. Such cracking is associated with the combined presence of three factors:

- The presence of hydrogen in the steel (even very small amounts, measured in parts per million)
- A microstructure that is partly or wholly martensitic
- High residual stresses (generally as a result of thick material)

If one or more of these conditions is absent or at a low level, hydrogen-induced cracking will not occur. However, high cooling rates such as those found in manual processes further enhance the probability of weld HAZ cold cracking.

The tolerance of steels for hydrogen decreases with increasing carbon or alloy content. Hydrogen-induced cracking can be controlled by choosing a welding process or an electrode that produces little or no hydrogen. Postweld heat treatments can be used to decrease or eliminate the residual hydrogen or to produce a microstructure that is insensitive to hydrogen cracking. Finally, welding procedures that result in low restraining stresses will also reduce the risk of weld cracking.

Stress-relief cracking due to reheating is of concern when welding quenched and tempered grades and heat-resistant steels containing significant levels of carbide formers, such as chromium, molybdenum, and vanadium. When weldments of these steels are heated above approximately 510 °C (950 °F), intergranular cracking along the prior-austenite grain boundaries may take place in the CGHAZ. Also known as reheat cracking and stress-rupture cracking, stress-relief cracking is thought to be closely related to the phenomenon of creep rupture. Furthermore, during reheating, the reprecipitation of carbides is likely to occur, further increasing the hardness. The precipitation of carbides during stress relaxation alters the delicate balance between resistance to grain-boundary sliding and resistance to deformation within the coarse grains of the heat-affected zone.

Some procedures that can be used singly or in combination to decrease stress-relief cracking in steels include the selection of a more appropriate weld joint design, weld location, and sequence of assembly to minimize restraint and stress concentrations. Selecting a filler metal that will provide a weld metal that has significantly lower strength than that of the HAZ at the heat-treating temperature is another way to minimize stress-relief cracking. Peening each layer of weld metal to generate a surface compressive stress state that counteracts shrinkage stresses is also very effective.

Lamellar cracking, better known as lamellar tearing, is characterized by a steplike crack parallel to the rolling plane. Figure 8 shows a typical feature of lamellar tearing, the horizontal and vertical cracking of the base plate. The problem occurs particularly when making tee and corner joints in thick plates such that the fusion boundary of the weld runs parallel to the plate surface. High tensile stresses can develop perpendicular to the midplane of the steel plate, as well as parallel to it. This tearing, usually associated with inclusions in the steel, progresses from one inclusion to another.

Fig. 8 Lamellar tear caused by thermal contraction strain

There is some evidence that sensitivity to lamellar tearing is increased by the presence of hydrogen in the steel. Inclusions that contain low-melting compounds, such as those of sulfur and phosphorus, also increase the sensitivity of steel to lamellar tearing by wetting the prior-austenite grain boundaries; this makes them too weak and fragile to withstand the thermal stresses during cooling. Some approaches that can minimize lamellar tearing are:

- Changing the location and design of the welded joint to minimize through-thickness strains
- Using a lower-strength weld metal
- Reducing available hydrogen
- Buttering the surface of the plate with weld metal prior to making the weld
- Using preheat and interpass temperatures of at least 95 °C (200 °F)
- Using base plates with inclusion shape control

Hot cracking, or solidification cracking, occurs at elevated temperatures and is usually located in the weld metal. Hot cracking also can be found in the HAZ, where it is known as liquation cracking. Solidification cracking in weld deposits during cooling occurs predominately at the weld centerline or between columnar grains. The fracture path of a hot crack is intergranular. The causes of solidification cracking are well understood. The partition and rejection of alloying elements at columnar grain boundaries and ahead of the advancing solid/liquid interface produce significant segregation. The elements of segregation form low-melting phases or eutectic structures to produce highly wetting films at grain

boundaries. They weaken the structure to the extent that cracks form at the boundaries under the influence of the tensile residual stresses during cooling. Liquation cracking is also associated with grain-boundary segregation and is aggravated by the melting of these boundaries near the fusion line. These impurity-weakened boundaries tend to rupture as the weld cools because of the high residual stresses.

Inclusions. Large amounts of sulfur and phosphorus are added to some steels to provide free-machining characteristics. These steels have relatively poor weldability because of hot tearing in the weld metal caused by low-melting compounds of phosphorus and sulfur at the grain boundaries. Iron oxide and iron sulfide inclusions, if present, are also harmful because of their solubility change with temperature and their propensity to precipitate at grain boundaries, contributing to low ductility, cracking, and porosity. Laminations, which are flat separations or weaknesses that sometimes occur beneath and parallel to the surface of rolled products, have a slight tendency to open up if they extend to the weld joint.

Weldability of Steels

Weldability of Steels

Low-carbon steels are mainly used in structural applications. Steels with less than 0.15 wt% C may harden to 30 to 40 HRC. Plain carbon steels containing less than 0.30 wt% C and 0.05 wt% S can be welded readily by most methods with little need for special measures to prevent weld cracking. The welding of sections that are more than 25 mm (1 in.) thick, particularly if the carbon content of the base metal exceeds 0.22 wt%, may require that the steel be preheated to approximately 40 °C (100 °F) and stress relieved at approximately 525 to 675 °C (1000 to 1250 °F).

For low-carbon steels, a low-alloy filler metal is generally recommended for meeting mechanical property requirements. The general procedure is to match the filler with the base metal in terms of strength or, for dissimilar welds, to match the lower-strength material. Often, however, higher-strength weld metal may actually require a softer HAZ to undergo a relatively large amount of strain when the joint is subjected to deformation near room temperature. Nevertheless, a low-strength filler metal should not be used indiscriminately as a remedy for cracking difficulties.

Medium-Carbon Steels. If steel containing about 0.5 wt% C is welded by a procedure commonly used for low-carbon steel, the heat-affected zone is likely to be hard, low in toughness, and susceptible to cold cracking. As indicated previously, preheating the base metal can greatly reduce the rate at which the weld area cools, thus reducing the likelihood of martensite formation. Postheating can further retard the cooling of the weld or can temper any martensite that might have formed.

The appropriate preheat temperature depends on the carbon equivalent of the steel, the joint thicknesses, and the welding procedure. With a carbon equivalent in the 0.45 to 0.60 wt% range, a preheat temperature in the range of approximately 95 to 100 °C (200 to 400 °F) is generally recommended. The minimum interpass temperature should be the same as the preheat temperature. A low-hydrogen welding procedure is mandatory with these steels. Modifications in welding procedure, such as the use of a larger V-groove or of multiple passes, also decrease the cooling rate and the probability of weld cracking.

Dilution can be minimized by depositing small weld beads or by using a welding procedure that provides shallow penetration. This is done to minimize carbon pickup from the base metal and the amount of hard transformation products in the fusion zone. Low heat input to limit dilution is also recommended for the first few layers in a multipass weld.

High-carbon steels generally contain over 0.60 wt% C and exhibit a very high elastic limit. They are often used in applications where high wear resistance is required. These steels have high hardenability and sensitivity to cracking in both the weld metal and the HAZ. A low-hydrogen welding procedure must be used for arc welding. Preheat and postheat will not actually retard the formation of brittle high-carbon martensite in the weld. However, preheating can minimize shrinkage stresses, and postheating can temper the martensite that forms. Successful welding of high-carbon steel requires the development of a specific welding procedure for each application. The composition, thickness, and configuration of the component parts must be considered in process and consumable selections.

High-strength low-alloy steels are designed to meet specific mechanical properties rather than a chemical composition. The alloy additions to HSLA steels strengthen the ferrite, promote hardenability, and help to control grain size. Weldability decreases as yield strength increases. For all practical purposes, welding these steels is the same as welding plain carbon steels that have similar carbon equivalents. Preheating may sometimes be required, but postheating is almost never required.

Quenched and tempered steels are furnished in the heat-treated condition with yield strengths ranging from approximately 350 to 1000 MPa (50 to 150 ksi), depending on the composition. The base metal is kept at less than 0.22% C for good weldability. Preheating must be used with caution when welding QT steels because it reduces the cooling rate of the weld HAZ. If the cooling rate is too slow, the re-austenitized zone adjacent to the weld metal can transform either to ferrite with regions of high-carbon martensite, or to coarse bainite, of lower strength and toughness. A moderate preheat, however, can ensure against cracking, especially when the joint to be welded is thick and highly restrained. A postweld stress-relief heat treatment is generally not required to prevent brittle fracture in weld joints in most QT steels.

Heat-treatable low-alloy steels. Examples of HTLA steels include AISI 4140, AISI 4340, AISI 5140, AISI 8640, and 300M. The high hardness of these steels requires that welding be conducted on materials in an annealed or overtempered condition, followed by heat treatment to counter martensite formation and cold cracking. However, high preheating is often used with a low-hydrogen process on these steels in a quenched and tempered condition, as in motor shaft applications. Preheating, or interpass heating, for both the weld metal and the HAZ are recommended. Hydrogen control is also essential to prevent weld cracking. Extremely clean vacuum-melted steels are preferred for welding.

Low sulfur and phosphorus, as described previously, are required to reduce hot cracking. Segregation, which occurs because of the extended temperature range at which solidification takes place, reduces high-temperature strength and ductility. Fillers of lower carbon and alloy content are highly recommended. Preheat and interpass temperatures of 315 °C (600 °F) or higher are very harsh environments for welders because of the physical discomfort and because an oxide layer forms at the weld joint. However, the cooling rate must be controlled to allow the formation of a bainitic microstructure instead of the hard martensite. The bainitic microstructure can be heat treated afterward to restore the original mechanical properties of the structure. Specifications and procedures should be followed rigorously for difficult-to-weld materials.

Precoated Steels. Thin plates and steel sheets are often precoated to protect them from oxidation and corrosion. The coatings commonly used are aluminum (aluminized), zinc (galvanized), and zinc-rich primers. As expected, the coating originally at the weld region is destroyed during fusion welding, and the effectiveness of the coating adjacent to the weld is significantly decreased by the welding heat. In the case of aluminized steels, the formation of aluminum oxide may adversely affect the wetting and weld pool shape. The welding electrode and filler metals should be selected carefully. A basic coating shielded metal arc (SMA) welding electrode is recommended.

For galvanized steels, weld cracking is generally attributed to intergranular penetration by zinc. Zinc dissolves considerably in iron to form an intermetallic compound at temperatures close to the melting temperature of zinc. Thus, molten zinc penetrates along the grain boundaries, leaving behind a brittle champagne fracture during cooling with the onset of a tensile stress state. Cracking occurs primarily at the throat region of a fillet weld, where shrinkage strain is more significant. The use of hot-dipped coatings results in more severe cracking, while thin electrogalvanized coatings are the least susceptible to cracking.

Low-silicon electrodes and rutile-base SMA welding rods are both good for galvanized steel welding. Specific welding and setup procedures should be followed, such as removing the zinc coating by an oxy-fuel process or by grinding, ensuring a large root opening, and using a slower welding speed to allow zinc vaporization and to prevent zinc entrapment in the weld metal. Adequate ventilation and fuel extraction should be mandatory in welding galvanized steels because of the health hazard of zinc fumes

Weldability Tests

Weldability tests conducted to provide information on the service and performance of welds. However, the data obtained in these tests can also be applied to the design of useful structures. Frequently these data are obtained from the same type of test specimens used in determining the base metal properties. Predicting the performance of structures from a laboratory-type test is very complex because of the nature of the joint, which is far from homogeneous, metallurgically or chemically. Along with the base metal, the weld joint consists of the weld metal and the HAZ. Thus, a variety of properties are to be expected throughout the welded joint. Careful interpretation and application of the test results are required.

There are currently many tests that evaluate not only the strength requirements of steel structures, but also the fracture characteristics and the effect of environmental conditions on early failure of the weldments. Selected major tests are described below.

Weld Tension Test. To obtain an accurate assessment of the strength and ductility of welds, several tension test specimens can be used; all weld metal specimens, transverse weld specimens, and longitudinal weld specimens are shown in Fig. 9. In the all weld metal test, base metal dilution should be minimized if the test is to be representative of the weld metal. However, the resulting properties may not be easy to translate into those properties achievable from welds made in an actual weld joint.

Fig. 9 Typical tension test specimens for evaluating welded joints. Both plate-type specimens have identical dimensions. All dimensions given in millimeters

Interpreting test results for the transverse butt weld test is complicated by the different strengths and ductilities generally found in the various regions of the joint. The primary information gained from the test is the ultimate tensile strength. Yield strength and elongation requirements are generally not specified.

Tests of HAZ properties that are unaffected by the presence of either base metal or weld metal are not easy to conduct because it is practically impossible to obtain specimens made up entirely of the HAZ. In addition, as indicated earlier, the HAZ is composed of various regions, each with its own distinct properties. Simulated HAZ specimens that are generated and tested using a Gleeble thermomechanical testing system can be used to provide a more accurate assessment of the tensile properties of this region.

Bend Test. Different types of bend tests are used to evaluate the ductility and soundness of welded joints. Bend test results are expressed in various terms, such as percent elongation in outer fibers, minimum bend radius prior to failure, go/no-go for specific test conditions, and angle of bend prior to failure. Various specimen designs, both notched and unnotched, and testing techniques have been used. Today, unnotched specimens can be used in quality control tests, while notched specimens may be used to predict in-service behavior; however, most notched bend tests are used for research purposes and are not in common industrial use. Transverse bend tests are useful because they quite often reveal the presence of defects that are not detected in tension tests. However, the transverse specimen suffers from the same weakness as the transverse weld tension test specimen in that nonuniform properties along the length of the specimen can cause nonuniform bending, although this is often compensated for by the use of a wraparound bend fixture.

Hardness testing can be used to complement information gained through tension or bend tests by providing information about the metallurgical changes caused by welding. Routine methods for the hardness testing of metals are well established. In carbon and low-alloy steels, the hardness near the fusion line in the HAZ may be much higher than in the base metal because of the formation of martensite. In the HAZ areas where the temperature is low, the hardness may be lower than in the base metal because of tempering effects.

The drop-weight test design is based on service failures resulting from brittle fracture initiation at a small flaw located in a region of high stress. The drop-weight test can be considered a limited-deflection bend test that uses a crack starter to introduce a running crack in the specimen. The specimen is a bar on which a brittle crack starter weld is deposited. This overlay cracks when the bar is deflected by the drop weight. A series of test is performed at different temperatures to determine the testing temperature below which the crack will propagate to the edges of the specimen. This critical temperature is also called the nilductility temperature (NDT), defined as the highest temperature at which the propagating crack reaches the edge of the specimen. Therefore, the drop-weight test is also known as the NDT test.

The Charpy V-notch (CVN) test is the most popular technique for evaluating the impact properties of welds. The energy absorbed by a sample at fracture determines the toughness of the specimen. In this test, specimens at different temperatures are broken using a pendulum hammer. A typical plot of CVN results for a carbon and low-alloy steel is illustrated in Fig. 10. The plot shows that there is a transition from low- to high-energy fracture over a narrow temperature range; this is associated with a change from trans-crystalline to ductile fracture. Therefore, material quality can be defined in terms of this transition temperature.

Fig. 10 Schematic impact transition curve for steel. FATT₅₀, fracture appearance transition temperature

In the CVN testing of welds, the notch is typically located at the weld centerline. For CVN testing of the heat-affected zone, the notch is more typically introduced at the CGHAZ. However, because precise location of a notch is never simple in the HAZ, simulated weld samples are used instead.

The crack tip opening displacement test measures toughness, primarily for elastic-plastic conditions. In CTOD tests, the clip gage opening at the onset of fracture is measured and used to calculate the crack opening displacement at

the crack tip. The critical value of CTOD at fracture, Δ_c , is a critical strain parameter that is analogous to the critical stress-intensity parameter, K_{Ic} . The CTOD test provides a useful method of determining the critical flaw size. Nevertheless, the test is very sensitive to changes in sample thickness, hardness, and strength, and it is difficult to obtain valid results in practical specimen thicknesses.

The application of fracture mechanics to the prevention of catastrophic failure in weldments is, however, complicated by the nature of the weldment. In addition to their metallurgical heterogeneity, weldments often contain high residual stresses. Consequently, it is inadequate to fracture test the base metal and assume that the critical crack length thus determined is valid when the base metal is made into a weldment. The fracture toughness criterion must be determined for the base metal, the HAZ, and the weld metal. By first determining the zone with the lowest toughness value, it is then possible to evaluate a more realistic critical flaw size. However, the plane-strain fracture toughness tests are preproduction or pilot plant type tests that provide a rational means for designs and engineers to estimate the effects of new designs, materials, or fabrication practices on the fracture-safe performance of structures. Other popular tests include compact tension (CT) and wedge opening load (WOL) tests, which are commonly used in the evaluation of structural weldments. Further discussion of CTOD and other fracture toughness testing of welds is available in the "Selected References" at the end of this article.

Stress-Corrosion Cracking Test. The presence of corrosive environments in a steel weldment may accelerate the initiation of a crack. Usually, the higher the strength of the steel, the more susceptible it becomes to stress-corrosion cracking. The steels considered in this article are not usually exposed to severely corrosive environments, but rather to the atmosphere, moisture, hydrocarbons, fertilizers, and soils. Nevertheless, welding can lower corrosive resistance by the introduction of:

- Compositional differences that promote galvanic attack between weld metal, HAZ, and base metal when the joint is immersed in a conducting liquid
- Residual stresses that can cause stress-corrosion cracking
- Surface flaws that can act as sites for stress-corrosion cracking

Stress-corrosion cracking is generally delayed cracking, with longer time to failure at lower stresses. Most stress-corrosion tests are fairly long in terms of time because of the slow crack initiation that occurs in unnotched test bars. However, it has been found that the long initiation period can be eliminated by testing precracked specimens. Additional information on the stress-corrosion cracking test is available in the "Selected References" at the end of this article.

Fabrication Weldability Tests

There are various types of tests for determining the susceptibility of the weld joint to different types of cracking during fabrication. They are:

- Restraint tests
- Externally loaded tests
- Underbead cracking tests
- Lamellar tearing tests

Table 1 summarizes the applications, controllable test variables, and typical test data of several fabrication weldability tests to illustrate the differences among them. Of the many tests identified in Table 1, the Lehigh restraint test, the Varestraint test, and the controlled thermal severity test are described below.

Table 1 Comparison of weldability tests for fabrication

Test	Fields of use	Controllable variables	Type of data	Specific equipment	Cost
Lehigh restraint test	Weld metal hot and cold cracks, root cracks, HAZ hydrogen cracks, stress-relief cracks	Joint geometry, process, filler metal, restraint level, heat input, preheat, postweld heat treatment	Critical restraint, or % hindered control	None	Costly machining
Slot test	HAZ hydrogen cracks	Filler, metal, interpass time, preheat	Time to crack, critical preheat	None	Low cost
Rigid restraint test	Weld metal hot and cold cracks, root cracks, HAZ hydrogen cracks	Joint geometry, process restraint level, filler metal, heat input, preheat	Critical restraint	Restraint jig	Costly machining and setup
Tekken test	Weld metal root cracks, HAZ hydrogen cracks	Joint geometry, process filler metal, heat input, preheat	Critical preheat	None	Low cost
Circular groove test	Weld metal hot and cold cracks, HAZ hydrogen cracks	Process, filler metal, preheat	Go/no-go	None	Costly preparation
Implant test	HAZ hydrogen cracks, stress-relief cracks	Process, filler metal, preheat, postweld heat treatment	Critical fracture stress, critical preheat	Loading jig	Intermediate cost
Tension restraint cracking test	HAZ hydrogen cracks	Process, filler metal, heat input, preheat	Critical fracture stress, critical preheat	Loading jig	Costly machining and setup
Varestraint test	Weld metal and HAZ hot cracks	Process, filler metal, heat input	Crack length, % strain	Loading jig	Costly preparation and analysis
Longitudinal bead-on-plate test	HAZ hydrogen cracks	Electrical type, heat input	% cracking	None	Low cost
Controlled thermal severity test	HAZ hydrogen cracks in fillet welds	Electrical type, cooling rate, preheat	Go/no-go (at two cooling rates)	None	Costly preparation
Cruciform test	HAZ hydrogen cracks, weld metal root cracks	Process, heat input, preheat, filler metal	Go/no-go	None	Costly preparation

Lehigh cantilever test	Lamellar tearing	Process, filler metal, heat input, preheat	Critical restraint stress and strain	Loading jig	Costly specimen preparation
Cranfield test	Lamellar tearing	Filler metal	Number of passes to crack	None	Low cost
Nick bend test	Weld metal soundness	Filler metal	Go/no-go	None	Low cost

Source: Ref 1

The Lehigh restraint test (Fig. 11) is particularly useful for quantitatively rating the crack susceptibility of a weld metal as affected by electrode variables. This test provides a means of imposing a controllable severity of restraint on the root bead that is deposited in a butt weld groove with dimensions suitable to the application. Slots are cut in the sides and ends of a plate prior to welding. By changing the length of the slots, the degree of plate restraint on the weld is varied without significantly changing the cooling rate of the weld. Therefore, a critical restraint for cracking can be determined for given welding conditions. This sample is also useful for hydrogen cracking.

Fig. 11 Basic outline of a Lehigh test specimen

The Varestraint test (Fig. 12) determines the susceptibility of the welded joint to hot cracking. The test utilizes external loading to impose controlled plastic deformation in a plate while a weld bead is being deposited on the long axis of the plate. The specimen is mounted as a cantilever beam, and a pneumatically driven yoke is positioned to force the specimen downward when the welding arc reaches a predetermined position. By the choice of the radius to which the plate is bent, the severity of deformation causing cracking can be determined. Strain from 0 to 4% can be chosen according to the susceptibility of the joint to hot cracking. When the bending moment is applied transverse to the weld

axis, the test is termed transvarestraint. A spot Varestraint test can also be conducted by keeping the arc stationary; bending is applied at the moment the arc is extinguished.

Fig. 12 Schematic of the Varestraint test. A, weld location; B, die; C, arc; D, load; r , radius of deformation

The controlled thermal severity test (Fig. 13) is designed to measure the cracking sensitivity of steels under cooling rates controlled by the thickness of the plates and the number of paths available for dissipating the welding heat. It is conducted with a plate bolted and anchor welded to a second plate in a position to provide two fillet (lap) welds. The fillet located at the plate edges has two paths of heat flow. The lap weld located near the middle of the bottom plate has three paths of heat flow, thus inducing faster cooling. The fillet welds are made first and allowed to cool, followed by the lap welds. After a holding time of 72 h at room temperature, the degree of cracking is determined by measuring the crack length on metallographic specimens.

Fig. 13 Schematic of the controlled thermal severity test

A number of other tests have been developed that contain welds in a circular configuration. The circular patch test has probably the most severe testing conditions; the two varieties are the Navy circular patch restraint test and the segmented circular patch restraint level. Cracking is detected by visual, radiographic, and liquid penetrant inspection. The cracking susceptibility of a material is measured as the total crack length and expressed as a percentage of the weld length. These tests can be used to determine both hot and cold cracking in the weld metal and the HAZ. Depending on the results, a go/no-go criteria is established for weld qualification. Detailed descriptions of these tests can be found in the "Selected References" at the end of this article.

Introduction

CARBON STEELS and low-alloy steels with ferrite-pearlite or ferrite-bainite microstructures are used extensively at elevated temperatures in fossil-fired power-generating plants, aircraft power plants, chemical-processing plants, and petroleum-processing plants. Carbon steels are often used up to about 370 °C (700 °F) under continuous loading, but also have allowable stresses defined up to 540 °C (1000 °F) in Section VIII of the ASME Boiler and Pressure Vessel Code. Carbon-molybdenum steels with 0.5% Mo are used up to 540 °C (1000 °F), while low-alloy with 0.5-1.0% Mo in combination with 0.5-9.0% Cr and sometimes other carbide formers (such as vanadium, tungsten, niobium, and titanium) are often used up to about 650 °C (1200 °F). For temperatures above 650 °C (1200 °F), austenitic alloys are generally used. However, these general maximum-use temperature limits do not necessarily apply in specific applications with different design criteria. Tables 1 and 2, for example, list maximum-use temperatures in two specific application areas with different design criteria.

Table 1 Temperature limits of superheater tube materials covered in ASME Boiler Codes

Material	Maximum-use temperature			
	Oxidation/graphitization criteria, metal surface ^(a)		Strength criteria, metal midsection	
	°C	°F	°C	°F
SA-106 carbon steel	400-500	750-930	425	795

Type 304 stainless steel	595	1100	815	1500

This article covers some elevated-temperature properties of carbon steels and low-alloy steels with ferrite-pearlite and ferrite-bainite microstructures for use in boiler tubes, pressure vessels, and steam turbines. In these applications, the selection of steels to be used at elevated temperatures generally involves compromise between the higher efficiencies obtained at higher operating temperatures and the cost of equipment, including materials, fabrication, replacement, and downtime costs. The highly alloyed steels, which depend on an austenitic matrix for their high-temperature properties, generally have higher resistance to mechanical and chemical degradation at elevated temperatures than the low-alloy ferritic steels. However, a higher alloy content generally means higher cost. Therefore, carbon and low-alloy ferritic steels are extensively used in several forms (piping, pressure vessel plates, bolts, structural parts) in a variety of applications that involve exposure to elevated temperatures. In addition, interest in ferritic steels has increased recently because their relatively lower thermal expansion coefficient and higher thermal conductivity make them more attractive than austenitic steels in applications where thermal cycling is present.

To illustrate the tonnage requirements for carbon and low-alloy steels in industrial construction, 1360 Mg (1500 tons) of pressure tubing were required for the construction of a single 500 MW coal-fired generating plant. The quantities of the various carbon and low-alloy steels used in the pressure tubing were as follows:

Steel type	Tons	% of total tonnage
Carbon	540	36
C- $\frac{1}{2}$ Mo	150	10

1 $\frac{1}{4}$ Cr-1Mo	495	33
2 $\frac{1}{4}$ Cr-1Mo	150	10
9Cr-1Mo	165	11

This list of carbon and low-alloy steels is for pressure tube applications and does not include the chromium-molybdenum-vanadium steels that are used for turbine rotors, high-temperature bolts, and pressure tubing.

Elevated-Temperature Properties of Ferritic Steels

Carbon and Low-Alloy Steels for Elevated-Temperature Service

The numerous types of steels used in elevated-temperature applications include the following:

- Carbon steels
- Low-alloy steels
- High steels
- Stainless steels
- Hot-work tool steels
- Iron-base superalloys

Within the context of this article, the low-alloy steels considered are the creep-resistant steels with 0.5 to 1.0% Mo combined with 0.5 to 9.0% Cr and perhaps other carbide formers (such as vanadium, tungsten, niobium, and titanium). High-strength low-alloy (HSLA) steels are not considered here because they typically have molybdenum contents below 0.5%, which limits their resistance against creep and temper embrittlement. However, HSLA steels, which are discussed in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume, may be effective substitutes for carbon steels in elevated-temperature applications. Another category of ferritic steels for elevated-temperature service are manganese-molybdenum-nickel ferritic steels (ASTM A 302 and A 533), which are commonly used for pressure vessels in light-water reactors. High-alloy steels, stainless steels, hot-work tool steels, and the iron-base superalloys are discussed in the Section "Specialty Steels and Heat-Resistant Alloys" in this Volume.

Alloy Designations and Specifications

Carbon and low-alloy steels used for elevated-temperature service are usually identified by American Iron and Steel Institute (AISI) designations; aerospace material specification (AMS), American Society of Mechanical Engineers (ASME), or American Society for Testing and Materials (ASTM) specification number; nominal composition; or trade name. These steels have also been assigned numbers in the Unified Numbering System. In addition, there are Military and Federal specifications covering many of these steels.

Steel products manufactured for use under the ASME Boiler and Pressure Vessel Code must comply with provisions of the appropriate ASME specification. Each specification includes information on ranges and limits of composition, dimensions and tolerances, minimum mechanical properties, and other functional requirements. The designations applied

to these products include the letters "SA," the number of the specification, and possibly other letters or numbers to distinguish among the various types, grades, and classes within a single specification. Most ASTM specifications are identical to the ASME specification of the same number except that the ASTM designations begin with the letter "A." Some examples of ASME specifications for elevated-temperature steels, as well as their compositions and typical room-temperature mechanical properties, are given in Tables 3(1) and 3(2).

The AISI designation for steels intended for elevated-temperature service is a three-digit number beginning with a 6, such as 601. The AISI designations are also included in Table 4.

Carbon Steels

Carbon steels are the predominant materials in pressure vessel fabrications because of their low cost, versatile mechanical properties, and availability in fabricated forms. They are the most common materials used in noncorrosive environments in the temperature range of -29 to 425 °C (-20 to 800 °F) in oil refineries and chemical plants. Although the ASME code gives allowable stresses for temperatures greater than 425 °C (800 °F), it also notes that prolonged exposure at these temperatures may result in the carbide phase of the carbon steel being converted to graphite. This phenomenon, known as graphitization, is a cumulative process dependent on the time the material is at or above 425 °C (800 °F). The result is a weakening of the steel after high-temperature exposure (Fig. 1). Carbon steels are also increasingly affected by creep at temperatures above 370 °C (700 °F). Figure 2 shows the effect of temperature on the stress-to-rupture life of a carbon steel.

Fig. 1 Effect of elevated-temperature exposure on the room-temperature tensile properties of normalized 0.17% C steel after exposure (without stress) to indicated temperature for 83,000 h

Fig. 2 Effect of exposure to elevated temperature on stress-to-rupture of carbon steel. Stress-to-rupture in 1000 and 10,000 h at the indicated temperature for specimens of normalized 0.17% C steel exposed to the test temperature (without stress) for 83,000 h and for similar specimens not exposed to elevated temperature prior to testing

Creep-Resistant Low-Alloy Steels

Creep-resistant low-alloy steels usually contain 0.5 to 1.0% Mo for enhanced creep strength, along with chromium contents between 0.5 and 9% for improved corrosion resistance, rupture ductility, and resistance against graphitization. Small additions of carbide formers such as vanadium, niobium, and titanium may also be added for precipitation strengthening and/or grain refinement. The effects of alloy elements on transformation hardening and weldability are, of course, additional factors.

The three general types of creep-resistant low-alloy steels are chromium-molybdenum steels, chromium-molybdenum-vanadium steels, and modified chromium-molybdenum steels. Chromium-molybdenum steels are used primarily for tube, pipe, and pressure vessels, where the allowable stresses may permit creep deformation up to about 5% over the life of the component. Typical creep strengths of various chromium-molybdenum steels are shown in Fig. 3. Figure 3 also shows the creep strength of a chromium-molybdenum steel with vanadium additions. Chromium-molybdenum-vanadium steels provide higher creep strengths and are used for high-temperature bolts, compressor wheels, or steam turbine rotors, where allowable stresses may require deformations less than 1% over the life of the component.

Fig. 3 General comparison of creep strengths of various creep-resistant low-alloy steels

Chromium-molybdenum steels are widely used in oil refineries, chemical industries, and electrical power generating stations for piping, heat exchangers, superheater tubes, and pressure vessels. The main advantage of these steels is the improved creep strength from molybdenum and chromium additions and the enhanced corrosion resistance from chromium. The creep strength of chromium-molybdenum steels is derived mainly from two sources: solid-solution strengthening of the matrix ferrite by carbon, molybdenum, and chromium; and precipitation hardening by carbides. Creep strength generally, but not always, increases with higher amounts of molybdenum and chromium. The effects of chromium and molybdenum on creep strength are complex (see "Effects of Composition" in this article). In Fig. 3, for example, 2.25Cr-1Mo steel has a higher creep strength than 5Cr-0.5Mo steel.

Chromium-molybdenum steels are available in several product forms (see Table 24 in the article "Classification and Designation of Carbon and Low-Alloy Steels" in this Volume). In actual applications, boiler tubes are used mostly in the annealed condition, whereas piping is used mostly in the normalized and tempered condition. Bend sections used in piping, however, are closer to an annealed condition than to a normalized condition. As a result of the cooling rates employed in these treatments, the microstructures of chromium-molybdenum steels may vary from ferrite-pearlite aggregates to ferrite-bainite aggregates. Bainite microstructures have better creep resistance under high-stress, short-time conditions but degrade more rapidly at high temperatures than pearlitic structures. As a result, ferrite-pearlite material has better intermediate-term, low-stress creep resistance. Because both microstructures will eventually spheroidize, it is expected that over long service lives the two microstructures will converge to similar creep strengths.

The 0.5Mo steel with 0.15% C is used for piping and superheater tubes operating at metal temperatures to 455 °C (850 °F). Above this temperature, spheroidization and graphitization may increase the possibility of failure in service. Use of

carbon-molybdenum steel has been largely discontinued for the higher temperatures because of graphitization. Chromium steels are highly resistant to graphitization and are therefore preferred for service above 455 °C (850 °F).

The 1.0Cr-0.5Mo steel is used for piping, cracking-still tubes, and boiler tubes for service temperatures to 510 or 540 °C (950 or 1000 °F). The similar 1.25Cr-0.5Mo steel is used up to 590 °C (1100 °F) and has comparable stress-rupture and creep properties as that of the 1.0Cr-0.5Mo alloy (Fig. 4).

Fig. 4 Creep strength (0.01% 1000 h) and rupture strength (100,000 h) of 1Cr-0.5Mo and 1.25Cr-0.5Mo steel. Source: Ref 1

The 2.25Cr-1.0Mo steel has better oxidation resistance and creep strength than the steels mentioned above. The 2.25Cr-1Mo steel is a highly favored alloy for service up to 650 °C (1200 °F) without the presence of hydrogen or 480 °C (900 °F) in a hydrogen environment. This steel, which has substantial documentation of its elevated-temperature properties (Ref 2, 3, 4, 5, and 6), is discussed in more detail in the section "Elevated-Temperature Behavior of 2.25Cr-1Mo Steel" in this article.

The 5, 7, and 9% Cr steels are generally lower in stress rupture and creep strength than the lower-chromium steels because the strength at elevated temperatures typically drops off with an increase in chromium. However, this may not always be the case, depending on the service temperature (Fig. 5) and the exposure (Fig. 6 and 7). Heat treatment is also an important factor. The main advantage of these steels is the improved oxidation resistance from the increased chromium content.

Fig. 5 Variation of 10^5 -h creep-rupture strength as a function of temperature for $2\frac{1}{4}$ Cr-1Mo steel, standard 9Cr-1Mo, modified 9Cr-1Mo, and 304 stainless steel. Source: Ref 7

Fig. 6 Effect of elevated-temperature exposure on stress-rupture behavior of (a) normalized and tempered $2\frac{1}{4}$ Cr-1Mo steel and (b) annealed 9Cr-1Mo steel. Exposure prior to stress-rupture testing was at the indicated test temperatures (without stress) and was 10,000 h long for the $2\frac{1}{4}$ Cr-1Mo steel and 100,000 h long for the 9Cr-1Mo steel. n/a, data not available at indicated exposure and rupture life.

Fig. 7 Effect of temperature exposure on the room-temperature properties of (a) normalized (900 °C, or 1650 °F) and tempered (705 °C, or 1300 °F) 2 $\frac{1}{4}$ Cr-1Mo steel after exposure (without stress) to indicated temperature for 10,000 h and (b) annealed 9Cr-1Mo steel after exposure (without stress) to indicated temperatures for 100,000 h

The chromium-molybdenum-vanadium steels are manufactured with higher carbon ranges (such as 0.28 to 0.33% and 0.40 to 0.50%) and are used in the normalized and tempered or quenched and tempered condition. Because of the relatively high yield strengths (Fig. 8) and creep strengths (Fig. 3), these steels are suitable for bolts, compressor wheels in gas turbines and steam turbine rotors, and other parts operating at temperatures up to 540 °C (1000 °F). The most common low-alloy composition contains 1% Cr, 1% Mo, and 0.25% V.

Fig. 8 Room-temperature and short-time elevated-temperature tensile strengths and yield strengths of selected steels containing less than 10% alloy. The 1.0Cr-0.5Mo steel, 0.5Mo steel, type 502, and 2.25Cr-1.0Mo steel were annealed at 843 °C (1550 °F). The 1.25Cr-0.5Mo steel was annealed at 815 °C (1500 °F). The 7.0Cr-0.5Mo and 9.0Cr-1.0Mo steels were annealed at 900 °C (1650 °F). The 1.0Cr-1.0Mo-0.25V steel was normalized at 955 °C (1750 °F) and tempered at 650 °C (1200 °F). H11, hardened 1010 °C (1850 °F), tempered 565 °C (1050 °F)

Bolt Applications. The basic compositions of low-alloy high-temperature bolt steels have evolved from chromium-molybdenum steels to chromium-molybdenum-vanadium steels. The chromium-molybdenum steels used until the late 1940s had creep strengths adequate for service at temperatures up to about 480 °C (895 °F). With the increasing need for a higher-strength steel, a 1Cr-1Mo- $\frac{1}{4}$ V steel strengthened by stable V_4C_3 precipitates was developed. This alloy was found to be adequate for steam temperatures up to 540 °C (1000 °F). When the steam temperatures reached about 565 °C (1050 °F) in the mid-1950s, a 1Cr-1Mo- $\frac{3}{4}$ V steel, in which vanadium and carbon had been stoichiometrically optimized to get the largest volume fraction of V_4C_3 and hence the highest creep strength, was developed. Unfortunately, this development had overlooked the importance of rupture ductility, and many creep-rupture failures of bolts due to notch sensitivity occurred. The loss in rupture ductility was subsequently countered by grain refinement and by compositional modifications involving titanium and boron. Melting practice is also another factor in improving rupture ductility.

High-Temperature Rotor Applications. Since it was introduced in the 1950s, 1Cr-1Mo-0.025V steel has remained the industry standard in turbine rotor applications, although a few higher-alloy rotor steels (12% Cr) have been developed (see the article "Elevated-Temperature Properties of Stainless Steels" in this Volume). It is well recognized that 1Cr-1Mo-0.025V rotor steels are limited by their creep strength for service up to about 540 °C (1000 °F).

The desired properties in chromium-molybdenum-vanadium steel rotors is made possible careful control of heat treatment and composition. In the United States, the usual practice has been to air cool the rotors from the austenitizing temperature in order to achieve a highly creep-resistant, but somewhat less tough, upper bainitic microstructure. In Europe, however, manufacturers have resorted to oil quenching of rotors from the austenitizing temperature to achieve a better compromise between creep strength and toughness. Oil quenching of 1Cr-1Mo-0.025V rotors may shift the transformation product increasingly toward lower bainite, but it is unlikely that the cooling rates needed for formation of martensite (that is, 10,000 °C/h or 20,000 °F/h) are ever encountered.

Comparative evaluation of creep properties of chromium-molybdenum-vanadium steels with martensite, bainite, and ferrite-pearlite as the principal microstructure have been conducted by numerous investigators, and the results have been reviewed elsewhere (Ref 8). There is consensus that upper bainitic structures provide the best creep resistance coupled with adequate ductility. Toughness properties are discussed in Ref 9.

Turbine Casing Applications. Chromium-molybdenum-vanadium steels are also used for turbine casings. The table below compares the maximum application temperatures of various low-alloy steels used for turbine casings (Ref 10):

Casing material	Maximum application temperature	
	°C	°F
C- $\frac{1}{2}$ Mo (0.25C max, 0.20-0.50Si, 0.5-1.0Mn, 0.50-0.70Mo)	480	895
Cr- $\frac{1}{2}$ Mo (0.15C max, 0.60Si max, 0.5-0.8Mn, 1.0-1.5Cr, 0.45-0.65Mo)	525	975
2 $\frac{3}{4}$ Cr-1Mo (0.15C max, 0.45Si max, 0.4-0.8Mn)	540	1000
Cr-Mo-V (0.15C max, 0.15-0.30Si max, 0.4-0.6Mn, 0.7-1.2Cr, 0.7-1.2Mo, 0.25-0.35V)	565	1050

Modified Chromium-Molybdenum Steels. To achieve higher process efficiencies in future coal conversion plants, chemical-processing plants, and petrochemical-refining plants, several modified versions of chromium-molybdenum pressure vessel steels have been investigated for operation at higher temperatures and pressures than those currently encountered. The higher temperatures affect the elevated-temperature strength, the dimensional deformation, and the metallurgical stability of an alloy, while higher operating pressures require either higher-strength alloys or thicker sections.

Of the unmodified ferritic steels, SA-387 grade 22, class 2 (normalized and tempered 2 $\frac{1}{4}$ Cr-1Mo unmodified steel) meets the requirements for the fabrication of large pressure vessels per Section VIII, Division 2 of the ASME Boiler and Pressure Vessel Code. Unfortunately, the thick-section hardenability is insufficient to prevent the formation of cementite, even with accelerated cooling procedures and lower tempering conditions (Ref 11). This persistence of cementite in thick-section SA-387 grade 22, class 2 is a concern regarding hydrogen attack (Ref 12). Other unmodified chromium-molybdenum steels such as 3Cr-1Mo and 5Cr-0.5Mo (SA-387 grades 21 and 5) resist hydrogen attack, but the design allowables are below those of 2 $\frac{1}{4}$ Cr-1Mo steel at some temperatures of interest. Higher-chromium alloys, such as 7Cr-0.5Mo and 9Cr-1Mo, also have strengths below normalized and tempered 2 $\frac{1}{4}$ Cr-1Mo and so have not been considered in the United States for heavy-wall vessels.

Therefore, several modified chromium-molybdenum alloys have been investigated for thick-section vessels in a hydrogen environment. These modified chromium-molybdenum alloys contain various microalloying elements such as vanadium, niobium, titanium, and boron. Three categories (Ref 11) of modified chromium-molybdenum steels investigated for thick-section applications in a hydrogen environment are:

- *3Cr-1Mo modified with vanadium, titanium, and boron* (Ref 13): This steel is approved for service up to 455 °C (850 °F), is fully hardenable, resists hydrogen attack, and has strengths capable of meeting the design allowables of normalized and tempered $2 \frac{1}{4}$ Cr-1Mo steel
- *9Cr-1Mo steel modified with vanadium and niobium* (Ref 14, 15): This steel has strengths exceeding those of 2.25Cr-1Mo and is approved for use to more than 600 °C (1110 °F) for steam and hydrogen service
- *2 $\frac{1}{4}$ Cr-1Mo steel modified with vanadium, titanium, and boron* (Ref 4, 16): Vanadium-modified $2 \frac{1}{4}$ Cr-1Mo steel is fully hardenable, resists hydrogen attack, and exceeds the strength of normalized and tempered $2 \frac{1}{4}$ Cr-1Mo steel

Other modified alloys, such as 3Cr-1.5Mo-0.1V-0.1C, have also been investigated (Ref 13, 17). The modified alloys have improved hardenability over unmodified $2 \frac{1}{4}$ Cr-1Mo steel. However, these modified chromium-molybdenum steels with bainitic microstructures undergo a strain softening (Ref 18, 19, 20, 21), which may be a limitation in applications with cyclic stresses.

The modified 9Cr-1Mo steel is an attractive alloy because it has strengths (Fig. 5) capable of meeting or exceeding the allowable stresses of stainless steel (Fig. 9). Microstructural work has indicated that the improved strength of the modified alloy derives from two factors. First, fine $M_{23}C_6$ precipitate particles nucleate on Nb(C,N), which first appears during the heat treatment. Second, the vanadium enters $M_{23}C_6$ and retards its growth at the service temperature. The finer distribution of $M_{23}C_6$ adds to the strength, and its retarded grain-size growth holds the strength for long periods of time at the service temperature. The grain-coarsening behavior of the modified 9Cr-1Mo steel as a function of normalizing temperature and time-temperature exposure is shown in Fig. 10.

Fig. 9 Estimated design allowable stresses (Section VIII of ASME Boiler and Pressure Vessel Code) as a function of temperature for modified 9Cr-1Mo steel, standard 9Cr-1Mo, 2 $\frac{1}{4}$ Cr-1Mo steel, and 304 stainless steel.

Fig. 10 Grain-coarsening behavior of a modified 9Cr-1Mo steel (9Cr-1Mo steel with 0.06 to 0.10% Nb and 0.18 to 0.25% V). Source: Ref 7

The H11 die steels have very high yield strengths (Fig. 8) and are primarily used in aircraft and missiles when high strength-to-weight ratios are desired. The H11 die steels are basically medium-carbon, 5% Cr steels with molybdenum and vanadium added. This composition air hardens from the austenitizing temperature and is tempered to a tensile strength of 1500 to 2200 MPa (215 to 320 ksi) (45 to 58 HRC). These properties apply to thin sheet as well as heavy forgings because the hardenability is fairly constant up to 38 mm ($\frac{24}{16}$ in.) on a standard end-quenched specimen.

Exposure of this steel at a temperature as close as 30 °C (50 °F) below the tempering temperature for 100 h or longer will have little effect on hardness and tensile strength. The high tempering temperature eliminates most residual stress. The retention of 70 to 80% of the room-temperature strength up to 540 °C (1000 °F) gives H11 steel a high strength-to-weight ratio at elevated temperatures. Additional information on H11 die steels is contained in the article "Ultrahigh-Strength Steels" in this Volume.

Mechanical Properties at Elevated Temperatures

The allowable design stresses for steels at elevated temperatures may be controlled by different mechanical properties, depending on the application and temperature exposure. For applications with temperatures below the creep-temperature range, tensile strength or the yield strength at the expected service temperature generally controls allowable stresses. For temperatures in the creep range, allowable stresses are determined from either creep-rupture properties or the degree of deformation from creep. In recent years, the worldwide interest in life extension of high-temperature components has also promoted considerably more interest in elevated-temperature fatigue. This effort has led to tests and methods for evaluating the effects of creep-fatigue interaction on the life of elevated-temperature components.

Ductility and toughness may also be important considerations, although ductility and toughness considerations commonly do not enter directly into the setting of allowable stresses. In elevated-temperature applications, ductility and toughness may not remain fixed in magnitude or character and often change with temperature and with time at temperature. The changes, which may be beneficial but are often deleterious, are of interest both at service temperature and, because of shutdowns, at ambient temperatures. Ductility is also an important factor that influences notch sensitivity and creep-fatigue interaction.

The types of tests used to evaluate the mechanical properties of steels at elevated temperatures include:

- Short-term elevated-temperature tests
- Long-term elevated-temperature tests
- Fatigue tests (including thermal fatigue and thermal shock tests)
- Time-dependent fatigue tests
- Ductility and toughness tests
- Short-term and long-term tests following long-term exposure to elevated temperatures

Several methods are used to interpret, interpolate, and extrapolate the data from some of these tests, as described in the section "Methods for Correlating, Interpolating, and Extrapolating Elevated-Temperature Mechanical Property Data" in this article.

Short-Term Elevated-Temperature Tests

Short-term elevated-temperature tests include the elevated-temperature tensile tests (described in ASTM E 21), a test for elastic modulus (ASTM E 231), compression tests, pin bearing load tests, and the hot hardness test. The mechanical properties determined by means of the tensile test include ultimate tensile strength, yield strength, percent elongation, and percent reduction in area. Because elevated-temperature tensile properties are sensitive to strain rate, these tests are conducted at carefully controlled strain rates. Tensile strength data obtained on specimens of annealed $2\frac{1}{4}$ Cr-1Mo steel at various temperatures and at strain rates ranging from $2.7 \times 10^{-6} \text{ s}^{-1}$ to 144 s^{-1} are shown in Fig. 11.

Fig. 11 Effect of test temperature and strain rate on the strength of annealed $2\frac{1}{4}$ Cr-1Mo steel. Tensile strength (a) and yield strength (b) of $2\frac{1}{4}$ Cr-1Mo steel tested at various temperatures and strain rates. Source: Ref 22

In designing components that are to be produced from low-alloy steels and to be exposed to temperatures up to 370 °C (700 °F), the yield and ultimate strengths at the maximum service temperature can be used much as they would be used in the design of components for service at room temperature. Figure 8 compares the short-time elevated-temperature yield and tensile strengths of selected alloys. Certain codes require that appropriate factors be applied in calculating allowable stresses.

Elevated-temperature values of elastic modulus can be determined during tensile testing or dynamic testing by measuring the natural frequency of a test bar at the designated test temperature. Figure 12 shows values of elastic modulus at temperatures between room temperature and 650 °C (1200 °F) for several low-alloy steels, determined during static tensile loading and dynamic loading.

(b) Effect of test temperature on shear modulus of $2\frac{1}{4}$ Cr-1Mo

steel. (c) Effect of test temperature on Poisson's ratio of $2\frac{1}{4}$ Cr-1Mo steel. Source: Ref 23

Compression tests and pin bearing load tests (ASTM E 209 and E 238) can be used to evaluate materials for applications in which the components will be subjected to these types of loading at elevated temperatures. Hot hardness tests can be used to evaluate materials for elevated-temperature service and can be applied to the qualification of materials in the same way in which room-temperature hardness tests are applied.

Components for many elevated-temperature applications are joined by welding. Elevated-temperature properties of both the weld metal and the heat-affected zones can be determined by the same methods used to evaluate the properties of the base metal.

Long-Term Elevated-Temperature Tests

Long-term elevated-temperature tests are used to evaluate the effects of creep, which is defined as the time-dependent strain that occurs under constant load at elevated temperatures. Creep is observed in steels at temperatures above about 370 °C (700 °F). In general, creep occurs at a temperature slightly above the recrystallization temperature of a metal or alloy; at such a temperature, atoms become sufficiently mobile to allow time-dependent rearrangement of the structure. In time, creep may lead to excessive deformation and even fracture at stresses considerably below those determined in room-temperature and elevated-temperature short-term tension tests.

Typical creep behavior consists of three distinct stages, as shown in Fig. 13. Following initial elastic-plastic strain resulting from the immediate effects of the applied load, there is a region of increasing plastic strain at a decreasing strain rate (first-stage, or primary, creep). Following the primary creep region, there is a region where the creep strain increases at a minimum, and almost constant, rate of plastic strain (second-stage, or secondary creep). This nominally constant creep rate is generally known as the minimum creep rate and is widely employed in research and engineering studies. Finally, there is a region of drastically increased strain rate with rapid extension to fracture (third-stage, or tertiary creep). Tertiary creep has no distinct beginning but does refer to the region with an increasing rate of extension that is followed by fracture. Under certain conditions, some metals may not exhibit all three stages of plastic extension. For example, at high stresses or temperatures, the absence of primary creep is not uncommon, with secondary creep or, in extreme cases, tertiary creep following immediately upon loading.

Fig. 13 Schematic representation of classical creep behavior

Of all the parameters pertaining to the creep curve, the most important for engineering applications are the creep rate and the time to rupture. These parameters are determined from long-term elevated-temperature tests that include creep, creep-rupture, and stress-rupture tests (ASTM E 139) and notched-bar rupture tests (ASTM E 292). In addition, relaxation tests (ASTM E 328) are used to evaluate the effect of creep behavior on the performance of high-temperature bolt steels. These tests are described in the article "Creep, Stress-Rupture, and Stress-Relaxation Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Creep Strength. When the rate or degree of deformation is the limiting factor, the design stress is based on the minimum (secondary) creep rate and design life after allowing for initial transient creep. The stress that produces a specified minimum creep rate of an alloy or a specified amount of creep deformation in a given time (for example, 1% total creep in 100,000 h) is referred to as the limiting creep strength or limiting stress. Typical creep strengths of various low-alloy steels are shown in Fig. 3. Table 2 also lists some suggested maximum service temperatures of various low-alloy steels based on creep rate. Figure 14 shows the 0.01%/1000 h creep strength of carbon steel as a function of room temperature tensile strength.

Fig. 14 Relationship between creep strength (0.01%/1000 h) and ultimate tensile strength of a carbon steel. Creep strength estimates made using isothermal lot constant. Source: Ref 24

Stress Rupture. When fracture is a limiting factor, stress-rupture values are used in design. Stress-rupture values of various low-alloy chromium-molybdenum steels are shown in Fig. 4, 5, and 6. Figures 15 and 16 show typical creep-rupture values of carbon and 1Cr-1Mo-0.25V steel, respectively.

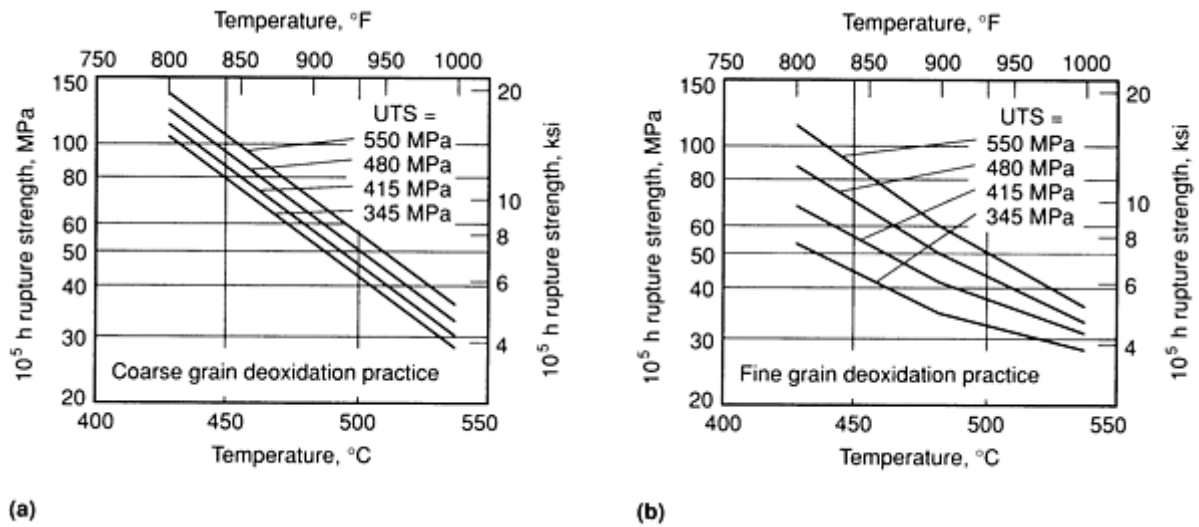

Fig. 15 Predicted 10^5 -h creep-rupture strengths of carbon steel with (a) coarse-grain deoxidation practice and (b) fine-grain deoxidation practice. Source: Ref 24

Fig. 16 Time-temperature-rupture data of a 1Cr-1Mo-0.25V steel

It should be recognized that long-term creep and stress-rupture values (for example, 100,000 h) are often extrapolated from shorter-term tests. Whether these property values are extrapolated or determined directly often has little bearing on the operating life of high-temperature parts. The actual material behavior is often difficult to predict accurately because of the complexity of the service stresses relative to the idealized, uniaxial loading conditions in the standardized tests and because of the attenuating factors such as cyclic loading, temperature fluctuations, or metal loss from corrosion.

For those alloys in which failure occurs before a well-defined start of tertiary creep, it is useful to use notched specimens or specimens with both smooth and notched test sections (with the cross-sectional area of the notch equal to that of the smooth test section). If the material is notch sensitive, the specimen will fail in the notch before failure occurs in the smooth section. It has been well recognized for many years that notch sensitivity is related to creep ductility. It has been suggested that a minimum smooth-bar creep ductility of about 10% in terms of reduction in area may be desirable for avoidance of notch sensitivity (Ref 25 and 26). Limited published data on notched stress-rupture properties of low-alloy

ferritic steels for elevated temperatures indicate that these steels generally are not notch sensitive. Representative stress-rupture data for notched and unnotched specimens of AISI 603 steel are presented in Fig. 17.

Fig. 17 Effect of notch on stress-rupture behavior. Stress-rupture behavior of smooth ($K = 1.0$) and notched specimens of AISI 603 steel tested at 595 °C (1100 °F). All specimens were normalized at 980 °C (1800 °F) and tempered 6 h at 675 °C (1250 °F). Source: Ref 27

Relaxation Tests. Creep tests on metals are usually carried out by keeping either the applied load or the stress constant and noting the specimen strain as a function of time. In another type of test, known as the stress relaxation test, a sample is first deformed to a given strain and then the stress is measured as a function of time such that the total strain remains constant. Stress relaxation tests are more difficult to carry out than ordinary creep tests and are more difficult to interpret. However, stress relaxation is an important elevated-temperature property in the design of bolts or other devices intended to hold components in contact under pressure. If the service temperature is high enough, the extended-time stress on the bolt causes a minute amount of creep, which results in a reduction in the restraining force.

Because of their low relaxed stresses, carbon steels are usually used only at temperatures below 370 °C (700 °F). Various low-alloy steels have been widely used up to metal temperatures of about 540 °C (1000 °F). Modified 12% Cr steels can be used for slightly higher temperatures. The common austenitic stainless steels are seldom used because of their low yield strength in the annealed condition, but are used in the cold-worked condition. The superstrength alloys are usually employed only at the highest temperatures. The comparative 1000-h relaxation strengths of these classes of alloys are shown in Fig. 18(a). More recent data are provided in Ref 29.

Fig. 18 Comparison of relaxation strengths (residual stress) of various steels. (a) Comparison of low-alloy steels with superstrength alloys. (b) Low-alloy steels at 1000 h. (c) Low-alloy steels at 10,000 h. Source: Ref 28

Carbon steel is not recognized as a high-temperature bolting material under ASTM standards or by the ASME Boiler Code. One of the most widely used low-alloy steels for moderately high-temperature bolting applications is quenched and tempered 4140, in accordance with ASTM A 193, grade B7. Its relaxation behavior is approximately indicated by the solid lines for 0.65-1.10Cr-0.10-0.30Mo steels in Fig. 18(b) and 18(c). The relaxation strength of 4140 is greater after normalizing and tempering than in the quenched and tempered condition. However, this steel is nearly always used in the quenched and tempered condition in order to obtain more consistent mechanical properties. Chromium-molybdenum steels similar to 4140 except that they contain approximately 0.50% Mo (A 193, grade B7A) have also been widely used. They have slightly higher relaxation strength than 4140 but are less readily available.

The strongest low-alloy steels are those with approximately 1% Cr, 0.5% Mo, and 0.25% V, in the normalized and tempered condition (A 193, grade B14) or the quenched and tempered condition (A 193, grade B16). Some of these grades are produced with rather high silicon contents (~0.75%), which seems to increase resistance to tempering. These grades have been satisfactory in service up to 540 °C (1000 °F) metal temperature in the absence of excessive follow-up

or retightening. However, they are somewhat notch sensitive in creep rupture and in impact at room temperature, especially in the normalized and tempered condition.

Fatigue

At room temperature and in nonaggressive environments (and except at very high frequencies), the frequency at which loads are applied has little effect on the fatigue strength of most metals. The effects of frequency, however, become much greater as the temperature increases or as the presence or corrosion becomes more significant. At high temperatures, creep becomes more of a factor, and the fatigue strength seems to depend on the total time stress is applied rather than solely on the number of cycles. The behavior occurs because the continuous deformation (creep) under load at high temperatures affects the propagation of fatigue cracks. This effect is referred to as creep-fatigue interaction. The quantification of creep-fatigue interaction effects and the application of this information to life prediction procedures constitute the primary objective in time-dependent fatigue tests. Time-dependent fatigue tests are also used to assess the effect of load frequency on corrosion fatigue.

Effect of Load Frequency on Corrosion Fatigue. In aggressive environments, fatigue strength is strongly dependent on frequency. Corrosion fatigue strength (endurance limit at a prescribed number of cycles) will generally decrease as the cyclic frequency is decreased. This effect is most important at frequencies of less than 10 Hz.

The frequency dependence of corrosion fatigue is thought to result from the fact that the interaction of a material and its environment is essentially a rate-controlled process. Low frequencies, especially at low strain amplitudes or when there is substantial elapsed time between changes in stress levels, allow time for interaction between material and environment; high frequencies do not, particularly when high strain amplitude is also involved. At very high frequencies or in the plastic-strain range, localized heating may seriously affect the properties of the part. Such effects normally are not considered to be related to a corrosion fatigue phenomenon.

When environments have a deleterious effect on fatigue behavior, a critical range of frequencies of loading may exist in which the mechanical/environmental interaction is significant. Above this range the effect usually disappears, while below this range the effect may diminish.

Creep-fatigue interaction is an elevated-temperature phenomenon that can seriously reduce fatigue life and creep-rupture strength. Figure 19 illustrates the effect of time-dependent fatigue when the elevated temperature is within the creep range of a material. Figure 19 shows a continuous strain cycling waveform (Fig. 19a) and a hold cycling waveform (Fig. 19b) for fatigue strength testing. Figure 19c) shows the fatigue life from a continuous strain cycle and from cycling with two different hold times. This decrease in fatigue life with increasing hold time or decreasing frequency, which occurs at temperatures within the creep range, is referred to as time-dependent fatigue or creep-fatigue interaction. It has been attributed to a number of factors, including the formation of intergranular voids or classical creep damage (which permits intergranular crack propagation under cyclic loading conditions), environmental interaction (corrosion fatigue), mean stress effects, and microstructural instabilities of defects produced as a result of stress and/or thermal aging, irradiation damage, and fabrication processing.

Fig. 19 Range of conditions to be considered in studies of elevated-temperature fatigue and the effect of continuous cycling (a) and strain hold (b) on elevated-temperature fatigue (c). Source: Ref 30

Most of these changes can occur at elevated temperatures and are time and possibly waveform dependent. There is also ample evidence to show that rupture ductility has a major influence on creep-fatigue interaction. Because this effect is believed to be caused by the influence of rupture ductility on the creep-fracture component, endurance in continuous-cycle and in high-frequency or short-hold-time fatigue tests (where fracture is fatigue-dominated) will be relatively unaffected. As the frequency is decreased or as the hold time is increased, the effect of rupture ductility becomes more pronounced. Endurance data for several ferritic steels, in relation to the range of rupture ductility exhibited by them, are

illustrated in Fig. 20. The lower the ductility, the lower the creep-fatigue endurance. In addition, long hold periods, small strain ranges, and low ductility favor creep-dominated failures, whereas short hold periods, intermediate strain ranges, and high creep ductility favor creep-fatigue-interaction failures. Similar results have been presented for austenitic stainless steels (see the article "Elevated-Temperature Properties of Stainless Steels" in this Volume).

Fig. 20 Effect of ductility on endurance of ferritic steels. Source: Ref 31

To determine the effect of cyclic loading superimposed on a constant load at elevated temperatures, several types of fatigue testing can be employed: continuous alternating stress, continuous alternating strain, tension-tension loading with the stress ratios greater than 0, and special waveforms that provide specific holding times at maximum load. Results of these tests show which factors are most contributory to deformation and fracture of the specimens for the testing conditions employed. Further information on time-dependent fatigue is available in the article "Creep-Fatigue Interaction" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fatigue-Crack Growth. Although the $S-N$ curves have been used in the past as the basic tool for design against fatigue, their limitations have become increasingly obvious. One of the more serious limitations is the fact that they do not distinguish between crack initiation and crack propagation. Particularly in the low-stress regions, a large fraction of a component's life may be spent in crack propagation, thus allowing for crack tolerance over a large portion of the life. Engineering structures often contain flaws or cracklike defects that may altogether eliminate the crack-imitation step. A methodology that quantitatively describes crack growth as a function of the loading variables is, therefore, of great value in design and in assessing the remaining lives of components.

Because fatigue-crack growth rates are obtained at various ΔK ranges and temperature ranges, it is difficult to compare the various types of materials directly. At a constant ΔK (arbitrarily chosen as $30 \text{ MPa}\sqrt{m}$, or $27 \text{ ksi}\sqrt{in}$), a clear trend of crack-growth-rate increase with increasing temperature can be seen as shown in Fig. 21. In this figure it can be seen that at temperatures up to about 50% of the melting point (550 to 600 °C, or 1020 to 1110 °F), the growth rates are relatively insensitive to temperature, but the sensitivity increases rapidly at higher temperatures. The crack-growth rates for all the materials at temperatures up to 600 °C (1110 °F) relative to the room-temperature rates can be estimated by a maximum correlation factor of 5 (2 for ferritic steels).

Fig. 21 Variation of fatigue-crack growth rates as a function of temperature at $\Delta K = 30 \text{ MPa}\sqrt{m}$ ($27 \text{ ksi}\sqrt{in}$). Source: Ref 32

Thermal fatigue refers to the gradual deterioration and eventual cracking of a material from cyclic thermal transients. In the past, thermal fatigue traditionally has been treated as synonymous with isothermal low-cycle fatigue at the maximum temperature of the thermal cycle. Life-prediction techniques also have evolved from the low-cycle-fatigue (LCF) literature. More recently, advances in finite-element analysis and in servohydraulic test systems have made it possible to analyze complex thermal cycles and to conduct thermomechanical fatigue (TMF) tests under controlled conditions. The assumed equivalence of isothermal LCF tests and TMF tests has been brought into question as a result of a number of studies. It has been shown that for the same total strain range, the TMF test can be more damaging under certain conditions than the pure LCF test. Information on the thermal fatigue of materials is provided in Ref 33.

High-cycle thermal fatigue frequently results from intermittent wetting of a hot surface by a coolant having a considerably lower temperature. In this case, thermal fatigue cracks may initiate at the surface after a sufficient number of cycles. In other cases, the thermal cycling or ratcheting may result in plastic deformation. Thermal ratcheting is the progressive cyclic inelastic deformation that occurs as a result of cyclic strains caused by thermal or secondary mechanical stresses; sustained primary loading often contributes to thermal ratcheting. Salt pots used to contain heat-treating salt are subject to thermal ratcheting whenever the salt goes through a freeze-melt cycle.

Ductility and Toughness

Although steels typically have adequate ambient temperature toughness and excellent elevated-temperature ductility, several embrittling mechanisms can occur during elevated-temperature exposure. Consequently, ductility and toughness tests are useful in assessing embrittling mechanisms. Information on the toughness of steels is provided in the article "Notch Toughness of Steels" in this Volume.

Figure 22 shows that toughness may actually decrease if steels are tempered in the range of 260 to 370 °C (500 to 700 °F). This decrease in toughness is referred to as tempered martensite embrittlement, 350 °C embrittlement, or 500 °F embrittlement and is discussed in more detail in the article "Embrittlement of Steels" in this Volume. As a result of this embrittlement, the tempering range between 260 and 370 °C (500 and 700 °F) is generally avoided in commercial practice. Another type of embrittlement--temper embrittlement--may occur in certain alloy steels as a result of holding on slow cooling through certain temperature ranges (see the text below discussing Fig. 23).

Fig. 22 Impact toughness as a function of tempering temperature of hardened, low-alloy, medium-carbon steels. Source: Ref 34

Another method of assessing toughness is to estimate the ductile-to-brittle transition temperature by performing notched-specimen impact tests at various temperatures. Steels are susceptible to a lowering of absorbed impact energy with decreasing temperature of use or testing. This change in energy value is accompanied by a transition from a fibrous to a crystalline-appearing fracture. The temperature at which some specified level of energy absorption or fracture appearance occurs is defined as a transition temperature. Transition temperature is an important concept because it defines a change in the mode of fracture from one that is caused predominantly by a shear mechanism to one that propagates primarily by cleavage (or along the grain boundaries in the case of temper embrittlement).

Shifts in the ductile-to-brittle transition temperature are measured to detect the presence of temper embrittlement, as shown in Fig. 23. In this case, 3140 steel (containing nominally 1.15% Ni and 0.65% Cr) was embrittled by both isothermal tempering and slow furnace cooling through the critical temperature range of about 375 to 575 °C (706 to 1070 °F). Additional information on temper embrittlement is available in the article "Embrittlement of Steels" in this Volume.

Fig. 23 Shift in impact transition curve to higher temperature as a result of temper embrittlement produced in SAE 3140 steel by isothermal holding and furnace cooling through the critical range. Source: Ref 34

A third method of assessing the effects of embrittlement mechanisms is by ductility (reduction of area) measurements. Creep embrittlement effects, for example, are usually reported in terms of a ductility minimum in stress-rupture tests, while temper embrittlement is usually recorded as an upward shift in Charpy V-notch transition temperature.

Creep embrittlement occurs in roughly the same temperature range as temper embrittlement, but is not reversible with heat treatment. Creep embrittlement also seems to depend on tempering reactions inside grains and on the presence of a carbide denuded zone at prior austenite grain boundaries, while segregation effects producing temper embrittlement occur at distances only a few atomic diameters from the grain boundary. Some investigators maintain that impurities known to produce temper embrittlement also contribute to the development of creep embrittlement. Some general characteristics of creep embrittlement are:

- Creep embrittlement has been shown to occur in the temperature range 425 to 595 °C (800 to 1100 °F) for alloy steels having ferrite plus carbide microstructures
- Creep embrittlement appears after longer times and becomes more severe the lower the position in the embrittling temperature range
- Creep embrittlement is manifested by a loss and then partial recovery of stress-rupture ductility with decreasing stress
- The development of embrittlement is invariably associated with a transition from transgranular to

intergranular fracture. Voids and microcracks are found throughout a creep embrittled microstructure. These voids form along prior austenite grain boundaries transverse to the tensile direction

- The mechanism for creep embrittlement appears to be closely associated with tempering reactions inside grains and at the grain boundaries during the creep process. The formation of fine, needlelike precipitates in grain interiors, accompanied by the development of a denuded zone and elongated alloy carbides at grain boundaries seems to contribute significantly to the embrittlement process
- Loss in toughness produced by creep embrittlement is largely unaffected by subsequent heat treatments; and void formation caused by creep is irreversible

Long-Term Exposure

Long-term exposure to elevated temperature may affect either short-term or long-term properties. For example, the initial microstructure of creep-resistant chromium-molybdenum steels consists of bainite and ferrite containing Fe_3C carbides, M_6C carbides, and fine M_2C carbides. Although a number of different carbides may be present, the principal carbide phase responsible for strengthening is a fine dispersion of M_2C carbides, where M is essentially molybdenum. With increasing aging in service, or tempering in the laboratory, a series of transformations of the carbide phases takes place that eventually transform M_2C into M_6C and M_{23}C (where the M in the latter two metal carbides is mostly chromium). Such an evolution of the carbide structure results in coarsening of the carbides, changes in the matrix composition, and an overall decrease in creep strength. The effect of exposure on the stress-rupture strength of two chromium-molybdenum steels is shown in Fig. 6.

Other metallurgical changes (such as spheroidization and graphitization) and corrosion effects may also occur during long-term exposure at elevated temperature. Therefore, tests after long-term exposure may be useful in determining the effect of these metallurgical changes on short-term or long-term properties.

Data Presentation and Analysis

Presentation of Tensile and Yield Strength. One method for comparing steels of different strengths is to report elevated-temperature strength as a percentage of room-temperature strength; this method is illustrated in Fig. 24. The strength levels of the steels represented in Fig. 24 varied from 480 to 1100 MPa (70 to 160 ksi).

Fig. 24 Ratios of elevated-temperature strength to room-temperature strength for hardened and tempered $2\frac{1}{4}\text{Cr-1Mo}$ steel tempered to room-temperature tensile strengths ranging from 480 to 1100 MPa (70 to 160 ksi). (a) Tensile strength. (b) Yield strength. Source: Ref 2

Presentation of Creep Data. Four different presentations of the same creep data for $2\frac{1}{4}\text{Cr-1Mo}$ steel given in Fig. 25. In Fig. 15(a) to (c), only the creep strain is plotted. In the isochronous stress-strain diagram (Fig. 25d), total strain is used. The overall format of Fig. 25(d) is particularly useful in design problems in which total strain is a major consideration.

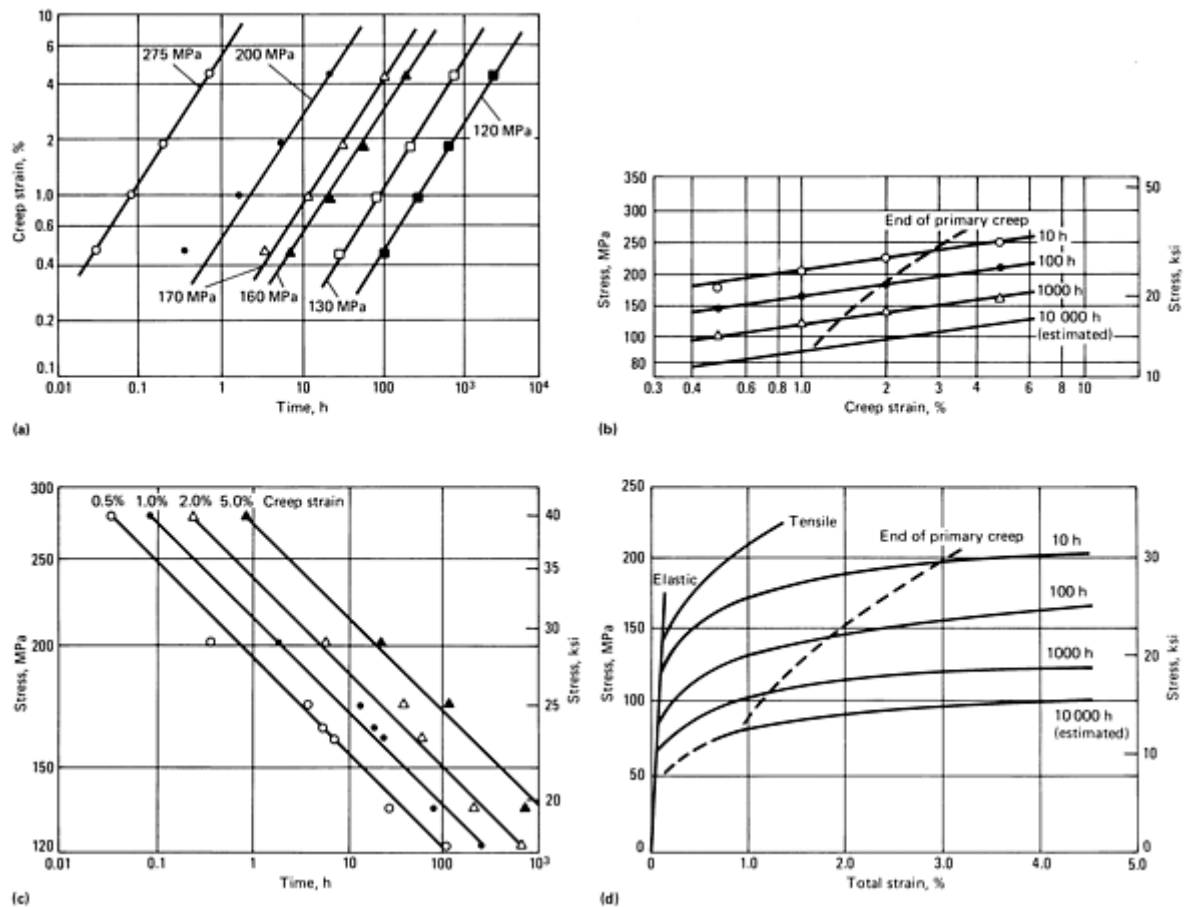

Fig. 25 Analysis of creep data. Creep behavior of $2\frac{1}{4}$ Cr-1Mo steel tested at 540 °C (1000 °F). (a) Creep strain-time plot; constant-stress lines have been drawn parallel. (b) Stress-creep strain plot. (c) Stress-time plot; constant-strain lines have been drawn parallel. (d) Isochronous stress-strain curves. Source: Ref 35

Methods for Correlating, Interpolating, and Extrapolating Elevated-Temperature Mechanical Property Data. The behavior of steels at elevated temperatures can be affected by many variables, including time, temperature, stress, and environment. A variety of methods have been devised for correlating, interpolating, and extrapolating elevated-temperature mechanical property data. Further information on the analysis of elevated-temperature data is contained in Ref 32; *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*; and MPC-7 of the American Society of Mechanical Engineers.

Larson-Miller Parameter. Several parameters have been used for comparison of and interpolation between stress-rupture data. The most widely used is the Larson-Miller parameter, P , defined by the equation:

$$P = T (C + \log t) \times 10^{-3} \quad (\text{Eq 1a})$$

where T is the test temperature in degrees Rankine, t is the rupture time in hours, and C is a constant whose value is approximately 20 for low-alloy steels. If T is given in Kelvins, the equation is:

$$P = 1.8 T (C + \log t) \times 10^{-3} \quad (\text{Eq 1b})$$

The Larson-Miller parameter is used with an experimentally determined graph such as that shown in Fig. 26 to correlate stress, temperature, and rupture time. Each graph should include the ranges of time and temperature for which the data apply; extrapolation beyond these ranges is generally not appropriate.

Fig. 26 Larson-Miller plot of stress-rupture behavior of $2\frac{1}{4}$ Cr-1Mo steel. Variation in Larson-Miller parameter with stress to rupture for normalized and tempered and hardened and tempered specimens of $2\frac{1}{4}$ Cr-1Mo steel tested between 425 and 650 °C (800 and 1200 °F) for rupture life to 10,000h; the data are grouped according to the room-temperature tensile strength of the steel. Larson-Miller plot for annealed steel included for comparison. Source: Ref 2

A similar parameter was used by Smith (Ref 36) to describe the creep behavior of 9Cr-1Mo steel. The creep rate parameter, P' , is given by:

$$P'=T (20-\log r) \times 10^{-3} \quad (\text{Eq 2a})$$

where T is the test temperature in degrees Rankine, and r is the minimum creep rate in percent per hour. If T is given in Kelvins, the equation is:

$$P'=1.8 T (20-\log r) \times 10^{-3} \quad (\text{Eq 2b})$$

The creep parameter is used with an experimentally determined graph such as the one shown in Fig. 27 for 2.25Cr-1Mo steel.

Fig. 27 Modified Larson-Miller plot of creep behavior of $2\frac{1}{4}$ Cr-1Mo steel. Variation in creep rate parameter with creep stress for normalized and tempered and hardened and tempered specimens of $2\frac{1}{4}$ Cr-1Mo steel tested between 425 and 650 °C (800 and 1200 °F) for test duration to 10,000 h; the data are grouped according to the room-temperature tensile strength of the steel. Creep rate data for annealed steel included for comparison. Source: Ref 2, 36

Extrapolation of Creep and Rupture Data. It should be recognized that long-term creep and stress-rupture values (for example, 100,000 h) are often extrapolated from shorter-term tests. Whether these property values are extrapolated or determined directly often has little bearing on the operating life of high-temperature parts. The actual material behaviour is often difficult to predict accurately because of the complexity of the service stresses relative to the idealized, uniaxial loading conditions in the standardized tests and because of the attenuating factors such as cyclic loading, temperature fluctuations, or metal loss from corrosion.

Marked changes in the slope of stress-rupture curves (see, for example, the lower plot in Fig. 15(b) near 480 °C, or 900 °F) must also be considered in data extrapolation. These changes in slope are often indicative of microstructural changes. Marked differences in slope between curves representing temperatures separated by less than 100 °C (180 °F) should be regarded as evidence that the slope of the lower-temperature curve will change over the time period of extrapolation, indicating the need for longer tests or careful approximations of the probable influence of the change in slope. Such changes in slope are almost always in the direction of lower stress-rupture strength than would be predicted by straight-line extrapolation.

Because of microstructural instabilities, deviations from the ideal creep curve must also be considered. Primary creep may be virtually absent or may be excessive and extend over long periods of time. Secondary creep may persist only for very short time periods or may exhibit nonclassical behavior. The creep behavior of annealed 2.25Cr-1Mo steel, for example, exhibits creep curves that differ from a classical three-stage creep curve in that two steady-state stages occur (Ref 37). During the first steady-state stage, the creep rate is controlled by the motion of dislocations that contain atmospheres of

carbon and molybdenum atom clusters, a process termed interaction solid-solution hardening (see the section "Strengthening Mechanisms" in this article). Eventually, the precipitation of Mo_2C removes molybdenum and carbon from solution, and the creep rate increases to a new steady state where the creep rate is controlled by atmosphere-free dislocations moving through a precipitate field. These nonclassical curves occur at intermediate stresses. As the stress decreases, the first steady-state stage disappears because the dislocation velocity decreases and the molybdenum-carbon atmosphere will be able to diffuse with the dislocations. At high stresses, a classical curve occurs when the creep rate is controlled by a combination of processes that operate in the two steady-state stages of the nonclassical curves (Ref 37). Such factors indicate the need to experimentally check values of deformation predicted by extrapolation of secondary creep data.

The extrapolation of stress-rupture ductility with parametric techniques has been considered a potential method for predicting long-term ductility from short-term tests (Ref 38). Because the stress-rupture ductility of many alloys used at elevated temperatures varies with temperature and stress, the objective is to develop a combined (stress, temperature) parameter that can be correlated to rupture ductility over a wide range of stresses and temperatures. Reference 38 compares the correlation between some parametric models and rupture ductility data for a $1\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$ steel in the temperature range of 510 to 620 °C (950 to 1150 °F).

Methods for Predicting Time-Dependent Fatigue (Creep-Fatigue Interaction) Behavior. Many methods have been employed to extrapolate available data to estimate the time-dependent fatigue life of materials. Development of a mathematical formulation for life prediction is one of the most challenging aspects of creep-fatigue interaction. It is complicated by the fact that any proposed formulation must account for strain rate, relaxation at constant strain, creep at constant load, the difference between tension and compression creep and/or relaxation, or combinations of all of these.

Linear damage summation is perhaps the most widely known and simplest of the many life prediction methods and has been used extensively in the evaluation of creep-fatigue interaction. It is based on a simple relation that fatigue damage can be expressed as a cycle fraction of damage and that creep damage can be expressed as a time fraction of damage. It is also assumed that these quantities can be added linearly to represent damage accumulation. Failure occurs when this summation reaches a certain value.

Other methods include the ductility exhaustion approach, the frequency modified approach, and strain range partitioning. These methods are reviewed in Ref 30, 32 and in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Elevated-Temperature Properties of Ferritic Steels

Corrosion

Although the mechanical properties establish the allowable design-stress levels, corrosion effects at elevated temperatures often set the maximum allowable service temperature of an alloy. The following sections describe the three common forms of corrosion--oxidation, sulfidation, and hydrogen attack--that occur at elevated temperature. Corrosion considerations with liquid-metal environments are also summarized. More detailed information on corrosion and its prevention is available in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Oxidation from steam or air is a serious problem that can occur at elevated temperatures. When metal is exposed to an oxidizing gas at elevated temperature, corrosion can occur by direct reaction with the gas. This type of corrosion is referred to as tarnishing, high-temperature oxidation, or scaling. The rate of attack increases substantially with temperature. The surface film typically thickens as a result of reaction at the scale/gas or metal/scale interface due to cation or anion transport through the scale, which behaves as a solid electrolyte.

Alloys intended for high-temperature applications are designed to have the capability of forming protective oxide scales. Chromium provides oxidation resistance in alloy steels, and Fig. 28 compares the loss by scaling for alloys with varying levels of chromium. Silicon can also improve oxidation resistance (Fig. 28), although it also reduces creep strength and may promote temper embrittlement when other impurities are present.

Fig. 28 Effect of temperature on metal loss from scaling for several carbon and alloy steels in air

The scaling data given in Fig. 28 were obtained in the presence of air. If other variables affecting oxidation are changed, such as gas composition, the heating method, temperature, pressure, or velocity, different rates of scaling can be expected. Elements such as sulfur, vanadium, and sodium can change the nature of metal oxidation, sometimes increasing it to a catastrophic level of several inches per year.

At elevated temperatures, steam decomposes at metal surfaces to hydrogen and oxygen and may cause steam oxidation of steel, which is somewhat more severe than air oxidation at the same temperature. Fluctuating steam temperatures tend to increase the rate of oxidation by causing scale to spall, which exposes fresh metal to further attack. Table 1 gives the maximum-use temperatures for several boiler alloys for which code standards exist. The strength criteria are based on the wall midsection temperatures, which are typically 25 °C (45 °F) lower than the outer surface temperature.

In a water environment, corrosion is significantly influenced by the concentrations of dissolved species, pH, temperature, suspended particles, and bacteria. Temperature plays a dual role with respect to oxygen corrosion. Increasing the temperature will reduce oxygen solubility. In open systems, in which oxygen can be released from the system, corrosion will increase up to a maximum at 80 °C (175 °F), where the oxygen solubility is 3 mg/L. Beyond this temperature, the reduced oxygen content limits the oxygen reduction reaction, preventing occurrence of the iron dissolution process. Thus, the corrosion rate of carbon steel decreases, and at boiling water conditions, the temperature effect is similar to room temperature with a high oxygen content. For closed systems, in which oxygen cannot escape, corrosion continues to increase linearly with temperature. The other factors affected by temperature are the diffusion of oxygen to the metal surface, the viscosity of water, and solution conductivity. Increasing the temperature will increase the rate of oxygen diffusion to the metal surface, thus increasing corrosion rate because more oxygen is available for the cathodic reduction process. The viscosity will decrease with increasing temperature, which will aid oxygen diffusion.

Sulfidation. Corrosion by various sulfur compounds at temperatures between 260 and 540 °C (500 and 1000 °F) is a common problem in many petroleum-refining processes and, occasionally, in petrochemical processes. When the sulfur activity (partial pressure and concentration) of the gaseous environment is sufficiently high, sulfide phases, instead of oxide phases, can be formed. In the majority of environments encountered in practice by oxidation-resistant alloys, Al_2O_3 or Cr_2O_3 should form in preference to any sulfides, and destructive sulfidation attack occurs mainly at sites where the protective oxide has broken down. The role of sulfur, once it has entered the alloy, appears to be to tie up the chromium and aluminum as sulfides, effectively redistributing the protective scale-forming elements near the alloy surface and thus

interfering with the process of formation or re-formation of the protective scale. If sufficient sulfur enters the alloy so that all immediately available chromium or aluminum is converted to sulfides, then the less stable sulfides of the base metal may form because of morphological and kinetic reasons. It is these base metal sulfides that are often responsible for the observed accelerated attack, because they grow much faster than the oxides or sulfides of chromium or aluminum; in addition, they have relatively low melting points, so that molten slag phases are often possible.

Sulfur can also transport across continuous protective scales of Al_2O_3 and Cr_2O_3 under certain conditions, with the result that discrete sulfide precipitates can be observed immediately beneath the scales on alloys that are behaving in a protective manner. For the reasons indicated above, as long as the amount of sulfur present as sulfides is small, there is little danger of accelerated attack. However, once sulfides have formed in the alloy, there is a tendency for the sulfide phases to be preferentially oxidized by the encroaching reaction front and for the sulfur to be displaced inward, forming new sulfides deeper in the alloy, often in grain boundaries or at the sites of other chromium- or aluminum-rich phases, such as carbides. In this way, fingerlike protrusions of oxide/sulfide can be formed from the alloy surface inward, which may act to localize stress or otherwise reduce the load-bearing section.

The relative corrosivity of sulfur compounds generally increases with temperature. Depending on the process particulars, corrosion is in the form of uniform thinning, localized attack, or erosion-corrosion. Corrosion control depends almost entirely on the formation of protective metal sulfide scales that exhibit parabolic growth behavior. In general, nickel and nickel-rich alloys are rapidly attacked by sulfur compounds at elevated temperatures, while chromium-containing steels provide excellent corrosion resistance (as does aluminum). The combination of hydrogen sulfide and hydrogen can be particularly corrosive, and as a rule, austenitic stainless steels are required for effective corrosion control.

The effect of temperature and alloy compositions on sulfidic corrosions depends on the sulfur compounds present. Figure 29 shows the rates of sulfur corrosion of various steels as a function of temperature. These so-called McConomy curves can be used to predict the relative corrosivity of crude oils and their various fractions (Ref 40). Although this method relates corrosivity to total sulfur content, and therefore does not take into account the variable effects of different sulfur compounds, it can provide reliable corrosion trends if certain corrections are applied. Plant experience has shown that the McConomy curves, as originally published, tend to predict excessively high corrosion rates. The curves apply only to liquid hydrocarbon streams containing 0.6 wt% S (unless a correction factor given in Fig. 30 for sulfur content is applied) and do not take into account the effects of vaporization and flow regime. The curves can be particularly useful, however, for predicting the effect of operational changes on known corrosion rates.

Fig. 29 Modified McConey curves showing the effect of temperature on high-temperature sulfidic corrosion of various steels and stainless steels. Source: Ref 39

Fig. 30 Effect of sulfur content on corrosion rates predicted by modified McConey curves in the temperature range of 290 to 400 °C (550 to 750 °F). Source: Ref 39

Over the years, it has been found that corrosion rates predicted by the original McConomy curves should be decreased by a factor of roughly 2.5, resulting in the modified curves shown in Fig. 29. The curves demonstrate the beneficial effects of alloying steel with chromium in order to reduce corrosion rates. Corrosion rates are roughly halved when the next higher grade of low-alloy steel (for example, 2.25Cr-1Mo, 5Cr-0.5Mo, 7Cr-0.5Mo, or 9Cr-1Mo steel) is selected. Essentially, no corrosion occurs with stainless steels containing 12% or more chromium. Although few data are available, plant experience has shown that corrosion rates start to decrease as temperatures exceed 455 °C (850 °F). Two explanations frequently offered for this phenomenon are the possible decomposition of reactive sulfur compounds and the formation of a protective coke layer.

Sulfidic Corrosion With the Presence of Hydrogen. The presence of hydrogen increases the severity of high-temperature sulfidic corrosion. Hydrogen converts organic sulfur compounds to hydrogen sulfide; corrosion becomes a function of hydrogen sulfide concentration (or partial pressure).

A number of researchers have proposed various corrosion rate correlations for high-temperature sulfidic corrosion in the presence of hydrogen (Ref 41, 42, 43, 44, 45, 46, and 47), but the most practical correlations seem to be the so-called Couper-Gorman curves. The Couper-Gorman curves are based on a survey conducted by National Association of Corrosion Engineers (NACE) Committee T-8 on Refining Industry Corrosion (Ref 48).

The Couper-Gorman curves differ from those previously published in that they reflect the influence of temperature on corrosion rates throughout a whole range of hydrogen sulfide concentrations. Total pressure was found not to be a significant variable between 1 and 18 MPa (150 and 2650 psig). It was also found that essentially no corrosion occurs at low hydrogen sulfide concentrations and temperatures above 315 °C (600 °F) because the formation of iron sulfide becomes thermodynamically impossible. Curves are available for carbon steel, 5Cr-0.5Mo steel, 9Cr-1Mo steel, 12% Cr stainless steel, and 18Cr-8Ni austenitic stainless steel. For the low-alloy steels, two sets of curves apply, depending on whether the hydrocarbon stream is naphtha or gas oil. The curves again demonstrate the beneficial effects of alloying steel with chromium to reduce the corrosion rate.

Modified Couper-Gorman curves are shown in Fig. 31. To facilitate the use of these curves, original segments of the curves were extended (dashed lines). In contrast to sulfidic corrosion in the absence of hydrogen, there is often no real improvement in corrosion resistance unless chromium content exceeds 5%. Therefore, the curves for 5Cr-0.5Mo steel also apply to carbon steel and low-alloy steels containing less than %5 Cr. Stainless steels containing at least 18% Cr are often required for essentially complete immunity to corrosion. Because the Couper-Gorman curves are primarily based on corrosion rate data for an all-vapor system, partial condensation can be expected to increase corrosion rates because of droplet impingement.

Fig. 31 Effect of temperature and hydrogen sulfide content on high-temperature H_2S/H_2 corrosion of (a) carbon steel, (b) 5Cr-0.5Mo steel, and (c) 9Cr-1Mo steel. These corrosion rates are based on the use of gas oil desulfurizers; corrosion rates with naphtha desulfurizers may be slightly less severe. Source: Ref 39

When selecting steels for resistance to high-temperature sulfidic corrosion in the presence of hydrogen, the possibility of high-temperature hydrogen attack should be considered. Conceivably, this problem arises when carbon steel and low-alloy steels containing less than 1% Cr are chosen for temperatures exceeding 260 °C (500 °F) and hydrogen partial pressures above 700 kPa (100 psia) and when corrosion rates are expected to be relatively low.

Hydrogen Damage. Because iron-base alloys are principal materials of construction, these alloys have been the focus of most of the studies relating to hydrogen effects. In addition, ferritic (body-centered cubic) steels have a particular sensitivity to hydrogen. For these reasons, hydrogen effects on steel are important. Such hydrogen effects have been thoroughly described in a review of hydrogen damage (Ref 49).

Hydrogen damage includes hydrogen embrittlement, hydrogen attack, and hydrogen blistering. In ferrous alloys, embrittlement by hydrogen is generally restricted to those alloys having a hardness of 22 HRC or greater. The other forms of hydrogen damage, such as hydrogen attack or hydrogen blistering, are associated with low-alloy or carbon steels.

Thermodynamic calculations by Odette (Ref 50) have also shown that the carbide M_3C is significantly less stable in hydrogen environments than alloy carbides such as M_2C , M_7C_3 , $M_{23}C_6$, and M_6C . As shown in Fig. 32, this M_3C carbide can persist in normalized 2.25Cr-1Mo steel for up to 50 h at 700 °C (1290 °F) and hence may be present during service. When alloy content is increased to 3Cr-1.5Mo, Ritchie *et al.* (Ref 51) have shown that the tempering kinetics are significantly accelerated and that M_3C can be eliminated from the microstructure within 1 h at 700 °C (1290 °F). Hydrogen exposures of 3Cr-1.0Mo-0.5Ni steel at 600 °C (1110 °F) and 17 MPa (2.5 ksi) for 100 h gave no indication of the voids characteristic of hydrogen attack on these steels (Ref 51).

Fig. 32 Isothermal diagram showing the sequence of carbide formation on tempering of normalized $2\frac{1}{4}$ Cr-1Mo steel. Source: Ref 12

Hydrogen attack is a damage mechanism that is associated with carbon and low-alloy steels exposed to hydrogen-containing environments at temperatures above 220 °C (430 °F) (Ref 49). With hydrogen at elevated temperatures and pressures, there is increasing availability of atomic hydrogen that can easily penetrate metal structures and react internally with reducible species. Exposure to the environment is known to result in a direct chemical reaction with the carbon in the steel. The reaction occurs between absorbed hydrogen and the iron carbide phase, resulting in the formation of methane:

Unlike nascent hydrogen, the resulting methane gas does not dissolve in the iron lattice. Internal gas pressures develop, leading to the formation of voids, blisters, or cracks. The generated defects lower the strength and ductility of the steel. Because the carbide phase is a reactant in the mechanism, its absence in the vicinity of generated defects serves as direct evidence of the mechanism itself.

Hydrogen attacks occur in carbon steels and can lead to fissuring of the steel. Alloy steels with stable carbides, such as chromium and molybdenum carbides, are less susceptible to this form of attack. For example, 2.25Cr-1Mo suffers some decarburization in high-temperature high-pressure hydrogen, but is less likely to fissure than carbon steel. Hydrogen attack does not occur in austenitic stainless steels (Ref 49).

The susceptibility of steels to attack by hydrogen can be judged from the Nelson curves, which indicate the regions of temperature and pressure in which a variety of steels will suffer attack. Nelson curves for various alloy steels are shown in Fig. 33. In Fig. 33(b), the Nelson curve indicates only the operating limits for the surface decarburization of $2\frac{1}{4}\text{Cr-1Mo}$ steel. There are, however, indications that the limiting condition for using quenched and tempered $2\frac{1}{4}\text{Cr-1Mo}$ steel will not be decarburization but rather the loss of integrity through methane bubble growth (Ref 54). This may only be true if fatigue is not a significant design consideration, because decarburization can affect fatigue strength. The top curve in Fig. 33(b) shows an estimate of the operating limits for the formation of methane bubbles (that is, hydrogen attack) in $2\frac{1}{4}\text{Cr-1Mo}$ steel (Ref 53).

(b) Nelson curves for three steels given in Ref 36 and an estimate of the operating limit (solid line) for the formation of methane bubbles in 2.25Cr-1Mo steel. Source: Ref 53

Hydrogen blistering is a mechanism that involves the hydrogen damage of unhardened steel near ambient temperature. It is known that the entry of atomic hydrogen into steel can result in its collection, as the molecular species, at internal defects or interfaces. If the entry kinetics are substantial (promoted by an acidic environment, high corrosion rates, and cathodic poisons), the resulting internal pressure will cause internal separation (fissuring or blistering) of the steel. Such damage typically occurs at large, elongated inclusions and results in delaminations known as hydrogen blisters. Field experience indicates that fully killed steels are more susceptible than semikilled steels (Ref 55), but the nature and size of the original inclusions appear to be the key factors with regard to susceptibility. Rimmed steels or free-machining grades with high levels of sulfur or selenium would most likely show a high susceptibility to blistering. Stepwise cracking at the ends of blisters indicates an effect of elongated inclusions in the delamination process (Ref 49, 55). Similar stepwise cracking occurs in the hydrogen-induced failure of low-alloy pipeline steels (Ref 56). Both stepwise cracking and blistering appear to be limited to environments in which acidic corrosion occurs and in which cathodic poisons, such as sulfide, are present to promote hydrogen entry.

Hydrogen embrittlement, unlike hydrogen attack or blistering, can occur without immediate and resolvable damage within the metal structure. In this respect, hydrogen embrittlement is a somewhat reversible process. For example, hydrogenation plant equipment, operating at about 540 °C (1000 °F) with absorbed hydrogen in the steel, is cooled from operating temperature at 30 to 40 °C (50 to 75 °F) per hour with no breakage. This cooling rate is apparently slow enough to allow most of the absorbed hydrogen to diffuse from the metal without causing excessive embrittlement. Another way of removing detrimental atomic hydrogen derives from its mobility at higher temperatures. A bake-out cycle, involving temperatures of 175 to 205 °C (350 to 400 °F), allows the diffusion and escape of hydrogen from the metal or alloy. If the hydrogen charging conditions were not severe enough to cause internal damage, the bake-out cycle (described in Federal Specification QQC-320) will restore full ductility.

Susceptibility to hydrogen embrittlement is strongly influenced by the strength level of the metal or alloy. In steels, untempered martensite is the most susceptible phase. Lamellar carbide structures are less desirable than those with spheroidized structures. In general, iron-base alloys with a ferritic or martensitic structure are restricted to a maximum hardness of 22 HRC. Most other alloys are restricted to a maximum hardness of 35 HRC. There are exceptions in both cases. The procedures for materials testing in a wet hydrogen sulfide environment, which is the most aggressive in promoting hydrogen entry, are discussed in NACE TM-01-77. Further information on hydrogen embrittlement is provided in the article "Embrittlement of Steels" in this Volume.

Resistance of Liquid-Metal Corrosion. The following sections describe the resistance of steels to various liquid-metal environments. Liquid metals can attack steels in various ways. One form of attack that can occur is intergranular penetration and/or dissolution by liquid metal. The unfortunate aspect of this mode of attack is that it can result in a loss of strength without any large weight loss or change in appearance. In this respect, it resembles the more familiar aqueous intergranular corrosion. Additional information on liquid-metal corrosion can be found in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Another phenomenon is liquid-metal embrittlement, which requires the presence of both stress and a liquid metal. The cracks that occur during the embrittlement process may be intergranular or transgranular. The process seems to be similar in many ways to stress-corrosion cracking. Steels have been reported to undergo embrittlement by lithium, indium, cadmium, zinc, tellurium, and various lead-tin solders. Additional information on liquid-metal embrittlement can be found in the article "Embrittlement of Steels" in this Volume.

Sodium and Sodium-Potassium Alloys. Plain carbon and low-alloy steels are generally suitable for long-term use in these media at temperatures to 450 °C (840 °F). Beyond these temperatures, stainless steels are required.

The principal disadvantage of ferritic steels in sodium systems is the decarburization potential and its possible effect on the mechanical properties of the ferritic steel and the other system materials. Reference 5 considers aspects of low-carbon $2\frac{1}{4}$ Cr-1Mo steel as the construction material for the sodium-heated steam generator of a liquid-metal fast breeder reactor.

Lithium is somewhat more aggressive to plain carbon steels than sodium or sodium-potassium. As a result, low-alloy steels should not be considered for long-term use above 300 °C (570 °F). At higher temperatures, the ferritic stainless steels show better results.

Cadmium. Low-alloy steels exhibit good serviceability to 700 °C (1290 °F).

Zinc. Most engineering metals and alloys show poor resistance to molten zinc, and carbon steels are no exception.

Antimony. Low-carbon steels have poor resistance to attack by antimony.

Mercury. Although plain carbon steels are virtually unattacked by mercury under nonflowing or isothermal conditions, the presence of either a temperature gradient or liquid flow can lead to drastic attack. The corrosion mechanism seems to be one of dissolution, with the rate of attack increasing rapidly with temperature above 500 °C (930 °F). Alloy additions of chromium, titanium, silicon, and molybdenum, alone or in combination, show resistance to 600 °C (1110 °F). Where applicable, the attack of ferrous alloys by mercury can be reduced to negligible amounts by the addition of 10 ppm Ti to the mercury; this raises the useful range of operating temperatures to 650 °C (1200 °F). Additions of metal with a higher affinity for oxygen than titanium, such as sodium or magnesium, may be required to prevent oxidation of the titanium and loss of the inhibitive action.

Aluminum. Plain carbon steels are not satisfactory for the long-term containment of molten aluminum.

Gallium is one of the most aggressive of all liquid metals and cannot be contained by carbon or low-alloy steels at elevated temperatures.

Indium. Carbon and low-alloy steels have poor resistance to molten indium.

Lead, Bismuth, Tin, and Their Alloys. Low-alloy steels have good resistance to lead up to 600 °C (1110 °F), to bismuth up to 700 °C (1290 °F), and to tin only up to 150 °C (300 °F). The various alloys of lead, bismuth, and tin are more aggressive.

Elevated-Temperature Properties of Ferritic Steels

Factors Affecting Mechanical Properties

The factors affecting the mechanical properties of steels include the nature of the strengthening mechanisms, the microstructure, the heat treatment, and the alloy composition. This section describes these factors, with particular emphasis on chromium-molybdenum steels (especially $2\frac{1}{4}$ -Cr-1Mo) used for elevated-temperature service.

In addition, various service factors such as thermal exposure and environmental conditions can induce metallurgical changes, which may affect the mechanical properties of steels used at elevated temperatures. These metallurgical changes include spheroidization, graphitization, decarburization, and carburization. Depending on the temperature and exposure environment, ferritic steels used at elevated temperatures may also be susceptible to embrittlement phenomena such as temper embrittlement, temper martensite embrittlement, creep embrittlement, hydrogen embrittlement, and liquid-metal embrittlement. Embrittlement phenomena are discussed in the article "Embrittlement of Steels" in this Volume.

Strengthening Mechanisms. The creep strength of a steel is affected by the typical strengthening mechanisms--namely, grain refinement, solid-solution hardening, and precipitation hardening. Of these various strengthening mechanisms, the refinement of grain size is perhaps the most unique because it is the only strengthening mechanism that also increases toughness. Figure 14 shows the effect of grain size on the creep strength of a carbon steel.

The creep strength of chromium-molybdenum steels is mainly derived from a complex combination of solid-solution (primarily interaction solid-solution strengthening) and precipitation effects, as illustrated in Fig. 34. In the early stages of creep, solid-solution effects are the largest contributor to creep resistance. As time progresses, the precipitation of carbides (primarily Mo₂C in the case of molybdenum steels) contributes more to the creep resistance. As time progresses still further, the strengthening effect of the carbides is reduced as the carbides coarsen (Ostwald ripening) and diffuse into stabler but weaker structures. Both of these strengthening mechanisms become unstable at high temperatures. In solid-solution hardening, an increase in temperature increases the diffusion rates of solute atoms in the dislocation atmospheres while at the same time dispersing the atoms of the atmospheres, with both effects making it easier for dislocations to move. In precipitation hardening, heating of the alloy to an excessively high temperature can cause solutionizing of the precipitates. At intermediate temperatures, the precipitates can coarsen and become less-effective impediments to dislocation motion. High stresses and high-strain cyclic loading also can lead to accelerated softening.

Fig. 34 Schematic of changes in creep strengthening contributions at 550 °C (1020 °F) in (a) normalized molybdenum steel and (b) normalized and tempered molybdenum steel. Source: Ref 57

The solid-solution strengthening effect illustrated in Fig. 34 occurs primarily from a process termed interaction solid-solution hardening (or strengthening), which is a mechanism that involves the interaction of substitutional and interstitial solutes (Ref 57, 58, and 59). This process occurs in ferritic alloys that contain in solid solution interstitial and substitutional elements that have an affinity for each other. As a result of this strong attraction, atom pairs or clusters could form dislocation atmospheres that hinder dislocation motion and therefore strengthen the steel. Other solid-solution effects from either a pure substitutional solute or a pure interstitial solute do not alone provide significant creep strengthening in carbon manganese steels and molybdenum steels. The addition of interstitial solutes to iron has no significant creep-strengthening effect above 450 °C (840 °F), while the substitutional solutes manganese, chromium, and molybdenum give rise to only modest increases in strength in the absence of interstitial solutes (Ref 59). However, when certain combinations of substitutional and interstitial solutes are present together (for example, manganese-nitrogen, molybdenum-carbon, and molybdenum-nitrogen), there is a substantial increase in creep strength (Ref 59). These combinations give rise to the strengthening process of interaction solid-solution hardening.

Precipitation-strengthening effects are probably negligible in the carbon-manganese steels typically used for elevated-temperature applications (Ref 57), although strengthening by fine NbC particles has been observed (Ref 60). Precipitation strengthening is more significant in molybdenum steels, for which the strengthening precipitates are mainly Mo₂C and Mo₂N. Further increases in precipitation strengthening can be achieved with additions of niobium or vanadium to chromium-molybdenum steels. The stability of the carbides increases in the following order of alloying elements: chromium, molybdenum, vanadium, and niobium. Fine and closely dispersed precipitates of NbC and VC are thus desirable, followed by the other carbides. This precipitation strengthening effect in creep-resistant chromium-molybdenum steels is related to secondary hardening, as discussed below.

Secondary Hardening. If the mechanical properties of tempered steels need to be maintained at elevated service temperatures, the problem is to reduce the amount of softening during tempering so that higher strength (hardness) can be achieved at higher temperatures. One way to reduce softening is with strong carbide formers such as chromium, molybdenum, and vanadium. These carbide formers induce an effect known as secondary hardening. Without these elements, iron-carbon alloys and low-carbon steels soften rapidly with increasing tempering temperature, as shown in Fig. 35. This softening is largely due to the rapid coarsening of cementite with increasing tempering temperature, a process dependent on the diffusion of carbon and iron. If present in a steel in sufficient quantity, however, the carbide-forming elements not only retard softening but also form fine alloy carbides that produce a hardness increase at higher tempering temperatures. This hardness increase is frequently referred to as secondary hardening. This hardening can also occur during elevated-temperature service and is related to creep strength, as shown in Fig. 36.

Fig. 35 Decrease in hardness with increasing tempering temperature for steels of various carbon contents.
Source: Ref 61

Fig. 36 Relationship between change in creep rate and change in room-temperature hardness during creep of normalized 1% Mo steel tested at 123 MPa (17.8 ksi) at 550 °C (1020 °F). Under these test conditions, secondary creep coincided with maximum precipitation hardening. Source: Ref 57

Secondary hardening allows higher tempering temperatures, and this increases the range of service temperatures. Figure 37 shows secondary hardening in a series of steels containing molybdenum. The secondary hardening peaks develop only at high tempering temperatures because alloy carbide formation depends on the diffusion of the carbide-forming elements, a more sluggish process than that of carbon and iron diffusion. As a result, not only is a finer dispersion of particles produced but also the alloy carbides, once formed, are quite resistant to coarsening. The latter characteristic of the fine alloy carbides is used to advantage in tool steels that must not soften even though high temperatures are generated by their use in hot-working dies or high-speed machining. Also, ferritic low-carbon steels containing chromium and molybdenum are used in pressure vessels and reactors operated at temperatures around 540 °C (1000 °F) because the alloy carbides are slow to coarsen at those temperatures.

Fig. 37 Retardation of softening and secondary hardening during tempering of steels with various molybdenum contents. Source: Ref 61

The beneficial property changes from secondary hardening can be improved by increasing the intensity of secondary hardening, by decreasing the rate of overaging of the secondary-hardening carbide, or by increasing the temperature of secondary hardening. The intensity of secondary hardening can be increased by increasing the mis-match between the carbide precipitate and the matrix (Ref 62). Although this tends to cause more rapid overaging, the net effect can be beneficial, so that a higher strength after tempering is achieved. Increased mis-match is produced by:

- Increasing the lattice parameter of the carbide precipitate
- Decreasing the lattice parameter of the matrix

The carbide Mo_2C can dissolve both chromium and vanadium. Chromium, being a smaller atom than molybdenum, reduces the lattice parameter of Mo_2C , but vanadium increases it. Chromium therefore tends to decrease the intensity of secondary hardening. Moreover, chromium causes the Mo_2C carbide to be less stable (that is, to give maximum secondary hardening at lower tempering temperatures) and accelerates overaging (Fig. 38). On the other hand, vanadium increases the lattice parameter of Mo_2C and stabilizes the carbide. The result is a greater intensity of secondary hardening.

Fig. 38 Effect of chromium on the tempering characteristics of 0.45C-1.75Mo-0.75V steels. Source: Ref 62

Effects of Microstructure. It is widely accepted that the strength and impact toughness of carbon and chromium-molybdenum steels with fully bainitic microstructures are better than those with a ferritic-bainitic microstructure. Bainitic microstructures also have better creep resistance under high-stress, short-time conditions, but degrade more rapidly at high temperatures than pearlitic structures. As a result, ferrite-pearlite material has better intermediate-term, low-stress creep resistance. Because both microstructures will eventually spheroidize, it is expected that over long service lives the two microstructures will converge to similar creep strengths. This convergence can be estimated to occur in about 50,000 h at 540 °C (1000 °F) for 2.25Cr-1Mo steel, based on the limited data presented in Fig. 39. Investigations of chromium-molybdenum steels for one application concluded that tempered bainite is the optimum microstructure for creep resistance (Ref 64). However, the carbide precipitates are also an important microstructural factor in achieving optimum creep behavior, and for some microstructures an untempered condition may be desirable (see the following section "Effects of Heat Treatment" in this article). Moreover, even though bainitic microstructures improve strength, toughness, and creep resistance, chromium-molybdenum steels with bainitic and tempered martensitic microstructures also undergo strain softening during mechanical cycling. This effect of strain softening of bainitic chromium-molybdenum steels has undergone several investigations (Ref 18, 19, 20, and 21).

Fig. 39 Variation in stress-rupture strength of $2\frac{1}{4}$ Cr-1Mo steel under different heat treatments. QT, quenched and tempered; NT, normalized and tempered; A, annealed; UTS, ultimate tensile strength. Source: Ref 63

Microstructure may also influence the carbide precipitation and strengthening mechanism of chromium-molybdenum steels. In $2\frac{1}{4}$ Cr-1Mo steel, for example, precipitation reactions are known to occur much more rapidly in bainite than in proeutectoid ferrite (Ref 12). In addition, the interaction solid-solution strengthening of $2\frac{1}{4}$ Cr-1Mo steel is influenced by microstructure. In tensile studies, it was concluded that interaction solid-solution hardening in bainitic (normalized and tempered) 2.25Cr-1Mo steel is due to chromium-carbon interactions, while it is due to molybdenum-carbon interactions in the proeutectoid ferrite of annealed steel (Ref 65).

Effects of Heat Treatment. Figure 40 shows the general effect of three heat treatments on the creep-rupture strength of 2.25Cr-1Mo steel. Like long-term exposure (Fig. 39), the creep-rupture strengths converge in Fig. 40.

Fig. 40 Influence of heat treatment on 10^5 -h creep-rupture strength of $2\frac{1}{4}$ Cr-1Mo steel. Source: Ref 66

The use of tempering is also an important factor that influences the level of precipitation strengthening and solid-solution strengthening in chromium-molybdenum steel (Fig. 34). In a normalized molybdenum steel (Fig. 34a), the initial contribution from solid-solution strengthening is greater than that of the normalized and tempered steel. In the normalized and tempered molybdenum steels (Fig. 34b), the initial contribution from precipitation strengthening will be larger than that from the normalized steel. In addition, the precipitation-strengthening effect in the normalized and tempered steel will reach a maximum and begin to decline at an earlier stage due to the earlier incidence of overaging in tempered material. This is a potential consideration in applications requiring creep resistance over long times and at high temperatures.

As noted in the previous section "Effects of Microstructure," an investigation for one application concluded that tempered bainite resulted in the optimum creep resistance. In ferrite-pearlite or ferrite-bainite structures, however, it has been suggested that the best creep resistance at relatively high stresses is obtained in the untempered condition, because the dislocations introduced on loading are then to nucleate a finer dispersion of particles in ferrite grains than is obtained by tempering in the absence of strain (Ref 57). Application of this concept does not apply to bainitic structures. In bainitic steels, where the dislocation density is already higher than that introduced upon straining of a ferrite/pearlite steel, the use of untempered structures is unlikely to prove beneficial to short-term creep strength (Ref 57). Ultimately, it is the balance of hardness (or strength) and toughness required in service that determines the conditions of tempering for a given application. Figure 41 shows the variation of properties from the tempering of a modified 9Cr-1Mo alloy (9Cr-1Mo with 0.06 to 0.10 wt% Nb and 0.18 to 0.25 wt% V).

Fig. 41 Room-temperature properties of two heats (open or closed symbols) of a modified 9Cr-1Mo steel correlated with the Holloman-Jaffe (HJ) tempering parameter. (a) Hardness. (b) Charpy energy. (c) 0.2% yield strength. (d) Total elongation at room temperature. Source: Ref 7

Effects of Composition. The mechanical properties of carbon and low-alloy steels are determined primarily by composition and heat treatment. The effects of alloying elements in annealed, normalized and tempered, and quenched and tempered steels are discussed below.

Carbon increases both the strength and hardenability of steel at room temperature but decreases the weldability and impact toughness. In plain carbon and carbon-molybdenum steels intended for elevated-temperature service, carbon content is usually limited to about 0.20%; in some classes of tubing for boilers, however, carbon may be as high as 0.35%. For chromium-containing steels, carbon content is usually limited to 0.15%. Carbon increases short-term tensile strength but does not add appreciably to creep resistance at temperatures above 540 °C (1000 °F) because carbides eventually become spheroidized at such temperatures.

Manganese, in addition to its normal function of preventing hot shortness by forming dispersed manganese sulfide inclusions, also appears to enhance the effectiveness of nitrogen in increasing the strength of plain carbon steels at elevated temperatures. Manganese significantly improves hardenability, but contributes to temper embrittlement.

Phosphorus and sulfur are considered undesirable because they reduce the elevated-temperature ductility of steel. This reduction in ductility is demonstrated by reductions in stress-rupture life and thermal fatigue life. Phosphorus contributes to temper embrittlement.

Silicon increases the elevated-temperature strength of steel. It also increases the resistance to scaling of the low-chromium steels in air at elevated temperatures. Silicon is one factor in temper embrittlement.

Chromium in small amounts (~0.5%) is a carbide former and stabilizer. In larger amounts (up to 9% or more), it increases the resistance of steels to corrosion. Chromium also influences hardenability.

The effect of chromium in ferritic creep-resistant steels is complex. By itself, chromium gives some enhancement of creep strength, although increasing the chromium content in lower-carbon grades does not increase resistance to deformation at elevated temperatures (Ref 59). When added to molybdenum steel, chromium generally leads to some reduction in creep strength (Ref 67) such as that shown in Fig. 42. For the 1.0Mo steel in Fig. 42, the optimum creep strength occurs with about 2.25% Cr. Chromium is most effective in strengthening molybdenum steels (0.5 to 1.0% Mo) when it is used in amounts of 1 to $2\frac{1}{2}$ %.

Fig. 42 Effect of chromium on the creep strength (stress to produce a minimum creep rate of 0.0001% per hour) of several steels containing small amounts of molybdenum, silicon, and aluminum at 540 °C (1000 °F). Source: Ref 68

Figure 43 summarizes the effects of chromium content on the tensile and yield strengths of chromium-molybdenum steels containing 0.5 to 1.0% Mo and various amounts of chromium. The effect of temperature is reported as the test temperature at which strength is reduced to 60% of its room-temperature value. Chromium is most effective in strengthening these chromium-molybdenum steels when it is used in amounts of 1 to $2\frac{1}{2}$ %.

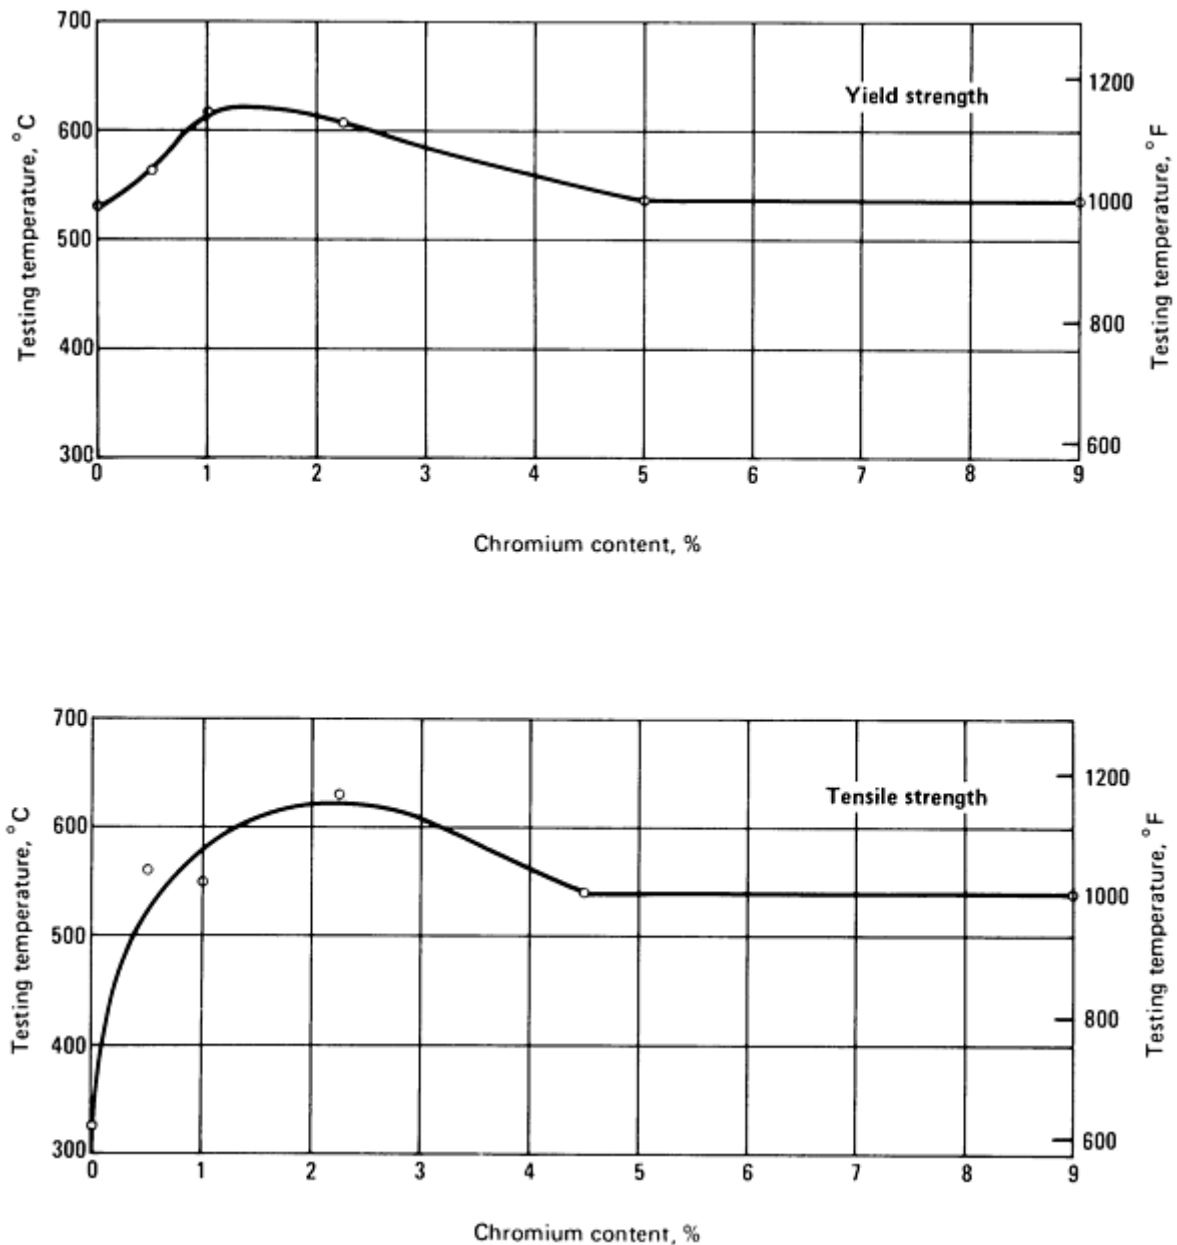

Fig. 43 Effect of chromium content on strength. Test temperature required to reduce tensile strength and yield strength to 60% of their room-temperature values for chromium-molybdenum steels containing 0.5 to 1.0% Mo and the indicated amount of chromium

Molybdenum is an essential alloying element in ferritic steels where good creep resistance above 450 °C (840 °F) is required. Even in small amounts (0.1 to 0.5%), molybdenum increases the resistance of these steels to deformation at elevated temperatures. Much greater creep strength can be obtained by increasing the molybdenum level to about 1% but at the expense of greatly reduced rupture ductility (Ref 69). Additions of chromium can improve rupture ductility.

Molybdenum is a carbide stabilizer and prevents graphitization. For certain ranges of stress and temperature, the dissolving of iron carbide and the concurrent precipitation of molybdenum carbide cause strain hardening in these steels. Molybdenum in amounts of 0.5% or less also minimizes temper embrittlement.

Niobium and vanadium are added to improve elevated-strength properties. Vanadium is also added to some of the higher-carbon steels to provide additional resistance to tempering and to retard the growth of carbides at service temperatures. Niobium is sometimes added to these steels to increase their strength through the formation of carbides. Niobium and vanadium improve resistance to hydrogen attack, but may promote hot (reheat) cracking.

Boron is added to increase hardenability. Boron can cause hot shortness and can impair toughness.

Tungsten behaves like molybdenum in simple steels and has been proposed for replacing molybdenum in nuclear applications (Ref 70, 71, and 72).

Thermal Exposure and Aging. Thermal exposure over time is one of the main service conditions affecting mechanical properties because the metallurgical structure of steel changes with time at temperature. For example, a ferritic matrix may be either fine or coarse-grained initially, and the carbides may vary from lamellar to completely spheroidized. With increasing time at service temperatures, the metallurgical structure slowly approaches a more stable state. For example, there may be some increase in ferrite grain size, the carbides may spheroidize, and the structure of carbon and carbon-molybdenum steels may approach the graphitized condition, with large irregular nodules of graphite in a ferrite matrix and few, if any, remaining carbides.

The thermal exposure of molybdenum and molybdenum-chromium ferritic steels also contributes to complex aging phenomena, which are governed by the complicated carbide precipitation processes that occur in the steel. Figure 32, for example, shows the sequence of carbide formations in 2.25Cr-1Mo steel. The M_2C carbide (where M is primarily molybdenum) is the principal carbide for strengthening in this steel. The Mo_2C first precipitates during heat treatment and/or elevated-temperature exposure. The Mo_2C forms a high density of fine needles or platelets and thus contributes to strengthening by dispersion hardening. During thermal exposure, however, the unstable Mo_2C carbide eventually transforms into large globular particles of $M_{23}C$ and η carbide. These particles are thought to have little strengthening effect, although there are some indications that $M_{23}C$ and η carbide present after long aging times in $2\frac{1}{4}$ Cr-1Mo steel can enhance rupture strength (Ref 37). Precipitation kinetics also depend on microstructure. The strengthening carbide Mo_2C precipitates more rapidly in bainite than proeutectoid ferrite. Similarly, the Mo_2C is replaced more quickly by more stable carbides in bainite than in proeutectoid ferrite. In either case, these precipitation reactions influence the strength in a similar way, regardless of whether the microstructure is bainite or proeutectoid ferrite.

Spheroidization of the carbides in a steel occurs over time because spheroidized microstructures are the most stable microstructure found in steels. This spheroidization of carbides reduces strength and increases ductility.

The effect of spheroidization on the rupture strength of a typical carbon-molybdenum steel containing 0.17% C and 0.42% Mo, at 480 and 540 °C (900 and 1000 °F), is shown in Fig. 44 for several initial metallurgical structures (normalized or annealed, fine or coarse grained). In these tests, the structure of the steel affected the rupture strength; for example, the stress for failure of a spheroidized structure in a given time was sometimes only half that of a normalized structure.

Fig. 44 Effect of spheroidization on the rupture strength of carbon-molybdenum steel (0.17C-0.88Mn-0.20Si-0.42Mo). Source: Ref 73

At 480 °C (900 °F), a coarse-grain normalized structure was the strongest for both short-time and long-time tests. The spheroidized structures were weaker than the normalized or annealed structures for short-time tests at both 480 and 540 °C (900 and 1000 °F). As the test time increased, the rupture values for all the structures tended to approach a common value.

The rate of spheroidization depends on the initial microstructure. The slowest spheroidizing is associated with pearlitic microstructures, especially those with coarse interlamellar spacings. Spheroidizing is more rapid if the carbides are initially in the form of discrete particles, as in bainite, and even more rapid if the initial structure is martensite.

Graphitization is a microstructural change that sometimes occurs in carbon or low-alloy steels subjected to moderate temperatures for long periods of time. The microstructure of carbon and carbon-molybdenum steels used for high-temperature applications such as vessels or pipes is normally composed of pearlite, which is a mixture of ferrite with some iron carbide (cementite). However, the stable form of carbon is graphite rather than cementite. Therefore, the pearlite can decompose into ferrite and randomly dispersed graphite, while the cementite will tend to disappear in these materials if they are in service long enough at metal temperatures higher than 455 °C (850 °F). This graphitization from the decomposition of pearlite into ferrite and carbon (graphite) can embrittle steel parts, especially when the graphite particles form along a continuous zone through a load-carrying member. Graphite particles that are randomly distributed throughout the microstructure cause only moderate loss of strength. Graphitization can be resisted by steels containing more than 0.7% Cr; such steels always contain at least 0.5% Mo as well, largely to impart elevated-temperature strength and resistance to temper embrittlement.

Graphitization and the formation of spheroidal carbides are competing mechanisms of pearlite decomposition. The rate of decomposition is temperature dependent for both mechanisms, and the mechanisms have different activation energies. As shown in Fig. 45, graphitization is the usual mode of pearlite decomposition at temperatures below about 550 °C (about 1025 °F), and the formation of spheroidal carbides can be expected to predominate at higher temperatures. Because graphitization involves prolonged exposure to moderate temperatures, it seldom occurs in boiling-surface tubing. Economizer tubing, steam piping, and other components that are exposed to temperatures from about 425 to 550 °C (800 to 1025 °F) for several thousand hours are more likely than boiler-surface tubing to be embrittled by graphitization.

Fig. 45 Temperature-time plot of pearlite decomposition by the competing mechanisms of spheroidization and graphitization in carbon and low-alloy steels. The curve for spheroidization is for conversion of one-half of the carbon in 0.15% C steel to spheroidal carbides. The curve for graphitization is for conversion of one-half of the carbon in aluminum-deoxidized, 0.5% Mo cast steel to nodular graphite.

The heat-affected zones adjacent to welds are among the most likely locations for graphitization to occur. Figure 46(a) shows a carbon-molybdenum steel tube that ruptured in a brittle manner along fillet welds after 13 years of service. Investigation of this failure revealed that the rupture was caused by the presence of chainlike arrays of embrittling graphite nodules (Fig. 46b and c) along the edges of heat-affected zones associated with each of the four welds on the tube. Arrays of graphite nodules were also found in the same locations on welds in several adjacent tubes, necessitating replacement of the entire tube bank.

Fig. 46 Carbon-molybdenum steel tube that ruptured in a brittle manner after 13 years of service because of graphitization at weld heat-affected zones. (c) Micrograph of a specimen etched in 2% nital showing chainlike array of embrittling graphite nodules (black) at the edge of a heat-affected zone. 100×

Decarburization is a loss of carbon from the surface of a ferrous alloy as a result of heating in a medium (for example, hydrogen) that reacts with carbon. Unless special precautions are taken, the risk of losing carbon from the surface of steel is always present in any heating to high temperatures in an oxidizing atmosphere. A marked reduction in fatigue strength is noted in steels with decarburized surfaces. The effect of decarburization is much greater on high tensile strength steels than on steels with low tensile strength.

Carburization. As in the case of sulfide penetration, carburization of high-temperature alloys is thermodynamically unlikely except at very low oxygen partial pressures, because the protective oxides of chromium and aluminum are generally more likely to form than the carbides. However, carburization can occur kinetically in many carbon-containing environments. Carbon transport across continuous nonporous scales of Al_2O_3 or Cr_2O_3 is very slow, and alloy pretreatments likely to promote such scales (for example, initially smooth surfaces or preoxidation) have generally been found to be effective in decreasing carburization attack.

The suitability of carburized metal for further service can be determined by evaluating its properties and condition. The mechanical properties of the carburized layer vary markedly from those of the unaffected metal. Room-temperature ductility and toughness are decreased, and hardness is increased greatly. This deterioration is important if the carburized layer is stressed in tension because cracking is quite likely to occur. Weldability is adversely affected. Welds in carburized materials frequently show cracks because of thermal tensile stresses, even with preheating and postheating. Ductility at temperatures above 400 °C (750 °F) is usually adequate. The corrosion resistance of the low chromium-molybdenum steels commonly used for elevated-temperature applications is reduced because of the reduction in effective chromium content. For the same reason, carburized stainless steels may have a relatively low resistance to general corrosion and to intergranular corrosion, particularly while the equipment is shut down. Minor amounts of carburization do not affect creep and rupture strengths significantly.

Factors Affecting Fatigue Strength. As described in the section "Creep-Fatigue Interaction" in this article, the hold times (dwell periods) and the waveform of cyclic strains influence the fatigue strength of metals at elevated temperatures.

These factors affect the assessment of low-cycle fatigue and creep fatigue (Fig. 19). In addition, environmental effects and strain aging also influence fatigue strength.

Environmental Effects. It has long been recognized that oxidation at elevated temperatures can have a marked effect (usually an acceleration) on fatigue crack initiation and growth (Ref 74, 75, 76, 77, 78, 79, and 80). In many alloys, intergranular oxidation initiates intergranular cracks at temperatures that depend on waveform or frequency but are near one-half the melting point (Ref 77). Penetration of oxygen along slip bands with subsequent localized embrittlement and cracking is another possibility. An example of the effects of environment on the fatigue strength of $2\frac{1}{4}$ Cr-1Mo steel is shown in Fig. 47. These tests were conducted in bending at a frequency of 0.05 Hz.

Fig. 47 Fatigue test results of $2\frac{1}{4}$ Cr-1Mo steel in sodium, air, and helium at 593 °C (1100 °F). Source: Ref 81

Dynamic Strain Aging. In addition to the effects of environment and temperature, ferritic low-carbon and alloy steels, when subjected to inelastic deformation in certain ranges of temperature, strain, and strain rate, undergo dynamic strain aging. Dynamic strain aging, which involves the interaction of interstitials and/or carbide or nitride formers such as chromium, molybdenum, and manganese with strain-induced dislocations, has been shown to markedly influence the cyclic strain rate dependent hardening characteristics, thus affecting both the initiation and growth of fatigue cracks in ferritic materials (Ref 81). Figure 48 shows the deleterious effect of a decreasing strain rate on the fatigue strength of an annealed $2\frac{1}{4}$ Cr-1Mo steel at various temperatures. Typically, strength is increased and ductility is decreased over the temperature ranges where aging occurs; therefore, both low-and high-cycle fatigue properties can be influenced accordingly. Thus, understanding fatigue, creep fatigue, environment, and strain aging interactions in the intermediate-to high-cycle life region is important.

Fig. 48 Cycles to failure as a function of temperature and strain rate (continuous cycling) for various heats of isothermally annealed $2\frac{1}{4}\text{Cr}-1\text{Mo}$ steel. Source: Ref 81

Air Hardening. The amount of air hardening of the various low-alloy steels depends on composition and austenitizing temperatures (Table 5). Steels that harden to more than 300 HB upon air cooling from 1065 $^{\circ}\text{C}$ (1950 $^{\circ}\text{F}$) require close control of welding operations. Gas-shielded fusion methods with nonconsumable tungsten electrodes and filler rods of parent metal are suitable for welding the 5% Cr steels having about 0.40% C. Except for the chromium-molybdenum-vanadium type, these steels are normally annealed at the mill, and no further heat treatment is necessary except stress relief after welding for the air-hardening steels. Heavy sections can be preheated.

Table 5 Air-hardening characteristics of low-alloy high-temperature steels

Specimens were cylinders 25 mm (1 in.) in diameter and 50 mm (2 in.) long. After air cooling from the designated temperatures they were sliced longitudinally, and the hardness determined. The values are influenced by chemical variations within the permissible limits of the specifications.

Elevated-Temperature Properties of Ferritic Steels

Elevated-Temperature Behavior of 2.25Cr-1Mo Steel

The elevated-temperature behavior of $2\frac{1}{4}$ Cr-1Mo steel has been studied more thoroughly than that of any other steel. The available data on annealed and normalized and tempered $2\frac{1}{4}$ Cr-1Mo steel are summarized in Ref 82 and 83. The rupture strength and creep ductility of $2\frac{1}{4}$ Cr-1Mo steel in various heat-treated conditions are reviewed in Ref 82. The following conclusions were reached:

- The stress-rupture strength generally increases linearly with room-temperature tensile strength up to about 565 °C (1050 °F) for times up to 10,000 h
- At a given strength level, tempered bainite results in higher creep strength than tempered martensite or ferrite-pearlite aggregates for temperatures up to 565 °C (1050 °F) and times up to 100,000 h. For higher temperatures and times, the ferrite-pearlite structure is the strongest
- Rupture ductility generally decreases with rupture time, reaches a minimum, and then increases again. Test temperature, room-temperature tensile strength, austenitizing temperature, and impurity content increase the rate of decrease of ductility with time and cause the ductility minimum to occur at shorter times

In terms of application, this steel has an excellent service record in both fossil fuel and nuclear fuel plants for generating electricity. The severe operating conditions in these plants have justified extensive studies of the behavior of $2\frac{1}{4}$ Cr-1Mo steel under complex loading conditions and in unusual environments. This steel has become a reference against which the performance of other steels can be measured.

Specifications, Steelmaking Practices, and Heat Treatments. Some of the specifications for $2\frac{1}{4}$ Cr-1Mo steel in the ASME Boiler and Pressure Vessel Code are listed in Table 6, which also includes product forms and room-temperature mechanical property requirements. For some of these specifications, composition ranges and limits differ slightly from those given in Tables 3(1) and 3(2).

Table 6 Room-temperature mechanical properties of $2\frac{1}{4}$ Cr-1Mo steel in various product forms

(a) Elongation in 200 mm (8 in.)

In the United States, $2\frac{1}{4}$ Cr-1Mo steel is normally manufactured in an electric furnace. In Japan, basic oxygen processes are used. For certain critical applications, vacuum arc remelting or electroslag remelting is appropriate.

The austenitizing temperature for $2\frac{1}{4}$ Cr-1Mo steel is about 900 °C (1650 °F). Heat treatments commonly employed with $2\frac{1}{4}$ Cr-1Mo steel include:

- *Normalize and temper:* Austenitize at 910 to 940 °C (1650 to 1725 °F), cool in air, temper at 580 to 720 °C (1075 to 1325 °F)
- *Oil quench and temper:* Austenitize at 940 to 980 °C (1725 to 1800 °F), quench in oil, temper at 570 to 705 °C (1065 to 1300 °F)

Short-Term Elevated-Temperature Mechanical Properties of $2\frac{1}{4}$ Cr-1Mo Steel. The effects of test temperature on the tensile and yield strengths of $2\frac{1}{4}$ Cr-1Mo steel are illustrated in Fig. 11, 24, and 49. Data for annealed specimens and for hardened and tempered specimens are also included. The large variations in both tensile strength and yield strength with temperature and strain rate (Fig. 11) are caused by strain rate, temperature, and microstructure.

Fig. 49 Effect of test temperatures on strength of $2\frac{1}{4}$ Cr-1Mo steel. Effect of test temperature on tensile strength, yield strength, creep strength (for creep rate of $0.1 \mu\text{m/m} \cdot \text{h}$), and stress to rupture (for life of 100,000 h) of annealed specimens (dashed lines) and hardened and tempered specimens (solid lines) of $2\frac{1}{4}$ Cr-1Mo steel. Source: Ref 2

The effects of elevated temperatures, elongation, and reduction in area for annealed specimens tested at standard strain rates are illustrated in Fig. 50. Specimens tested at about 400 °C (750 °F) showed both an increase in strength and a reduction in ductility, both of which were caused by strain aging. However, the reduction in ductility was relatively small.

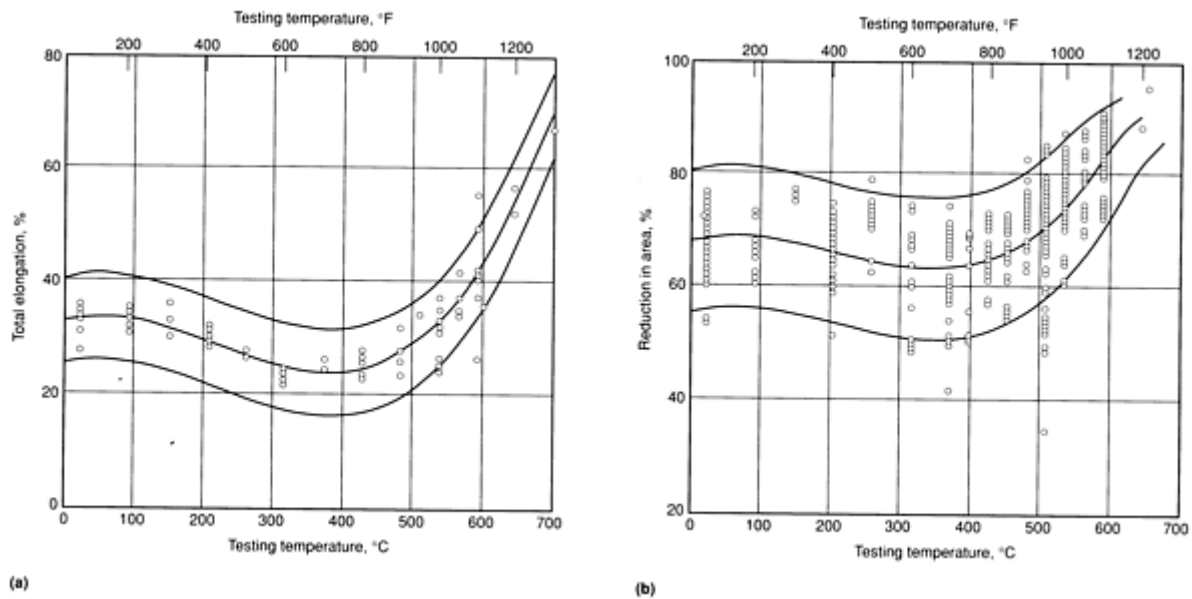

Fig. 50 Effect of test temperature on ductility. (a) Elongation in 50 mm (2 in.) and (b) reduction in area for annealed specimens of $2\frac{1}{4}$ Cr-1Mo steel tested at the indicated temperatures. Source: Ref 84

The effects of temperature on modulus of elasticity, shear modulus, and Poisson's ratio are shown in Fig. 12. The modulus of elasticity diminishes from 215 GPa (31×10^6 psi) at room temperature to 140 GPa (20.3×10^6 psi) at 760 °C (1400 °F); similarly, the shear modulus diminishes from 83 GPa (12.05×10^6 psi) at room temperature to 52.4 GPa (7.6×10^6 psi) at 760 °C (1400 °F). Poisson's ratio increases from 0.288 at room temperature to 0.336 at 760 °C (1400 °F).

Long Term Elevated-Temperature Mechanical Properties of $2\frac{1}{4}$ Cr-1Mo Steel. The creep and stress-rupture behavior of annealed specimens and hardened and tempered specimens of $2\frac{1}{4}$ Cr-1Mo steel are illustrated in Fig. 25, 26, 27, and 49. With regard to rupture life and creep rate, the hardened and tempered specimens were able to withstand higher stresses than the annealed specimens.

The ductility exhibited by stress-rupture specimens can be roughly correlated with stress level or rupture life. In general, specimens tested at high stress levels have short rupture lives, and such specimens exhibit greater reduction in area than similar specimens tested at lower stress levels. These data show considerable scatter but no evidence of brittle behavior by this steel. The relaxation behavior of $2\frac{1}{4}$ Cr-1Mo steel is illustrated in Fig. 51.

Fig. 51 Relaxation behavior of 2 $\frac{1}{4}$ Cr-1Mo steel. Specimens were stressed to level indicated on ordinate of graph and exposed to elevated temperature for indicated duration; remaining stress indicated on graph. Source: Ref 84

Long-term exposure to elevated temperature can reduce the room-temperature and elevated-temperature properties of 2 $\frac{1}{4}$ Cr-1Mo steel. Some of these effects are illustrated in Fig. 6(a), 7(a), 52, and 53. Figure 7(a) shows the changes in room-temperature tensile properties caused by exposure (without stress) to elevated temperatures.

Fig. 52 Effect of exposure to elevated temperature on the strength of 2 $\frac{1}{4}$ Cr-1Mo steel. Variation in tensile and

yield strengths of two different heats of $2\frac{1}{4}$ Cr-1Mo steel after exposure (without stress) to test temperature of 455 °C (850 °F)

Fig. 53 Effect of exposure to elevated temperature on the stress-rupture behavior of $2\frac{1}{4}$ Cr-1Mo steel. Variation in rupture life for specimens of annealed $2\frac{1}{4}$ Cr-1Mo steel exposed to various elevated temperatures for the durations indicated. After aging, all specimens were stressed to 140 MPa (20 ksi) and tested at 565 °C (1050 °F).

Figure 52 shows the effect of variations in aging time (without stress) at 455 °C (850 °F) on the ultimate tensile and yield strengths of two heats of $2\frac{1}{4}$ Cr-1Mo steel tested at the same temperature. The difference in strength between these two heats was observed even before the tests; the differences were probably caused by variations in composition and microstructure. The same factors account for strength changes during aging because they affect both the size and distribution of carbides in the steel.

As shown in Fig. 53, prolonged aging without stress at 565 °C (1050 °F) can reduce time to rupture for annealed $2\frac{1}{4}$ Cr-1Mo steel. Similarly, the data in Fig. 6(a) show that prolonged exposure to high temperatures without stress substantially reduces stress to rupture in a fixed time. The amount of reduction in stress to rupture is greatest for exposure at 480 °C (900 °F).

Elevated-Temperature Fatigue Behavior of $2\frac{1}{4}$ Cr-1Mo Steel. The results of strain-controlled fatigue tests at 425, 540, and 595 °C (800, 1000, and 1100 °F) on specimens of annealed $2\frac{1}{4}$ Cr-1Mo steel are shown in Fig. 54. Within this range, the test temperature had relatively little effect on the number of cycles to failure. Other strain-controlled

fatigue tests (Fig. 48) have shown that reducing the carbon content to 0.03% decreases the fatigue strength. Furthermore, because of variations in strain-aging effect, specimens from one heat with a higher carbon content ran longer at 425 °C (800 °F) than at 315 °C (600 °F).

Fig. 54 Effect of elevated temperature on strain-controlled fatigue behavior of annealed $2\frac{1}{4}$ Cr-1Mo steel. Strain rate was greater than 4 mm/m · s. Source: Ref 84

The crack growth rate data shown in Fig. 55 and 56 were obtained from precracked specimens subjected to cyclic loading at a constant maximum load. Crack extension was measured at intervals during testing. The stress intensity factor range increased as crack length was increased. Figure 55 illustrates the increase in crack growth rate with increasing test temperature. The data in Fig. 56 indicate that in elevated-temperature tests at a given stress intensity factor range, crack growth rate increases as cyclic frequency is decreased. These fracture mechanics data can be applied to the design of structural components that may contain undetected discontinuities or that may develop cracks in service.

Fig. 55 Effect of temperature on fatigue crack growth rate. Variations in fatigue crack growth rate with test temperature for specimens of $2\frac{1}{4}$ Cr-1Mo steel tested in air. Stress ratio was 0.05; cyclic frequency was 400 per minute. Source: Ref 85

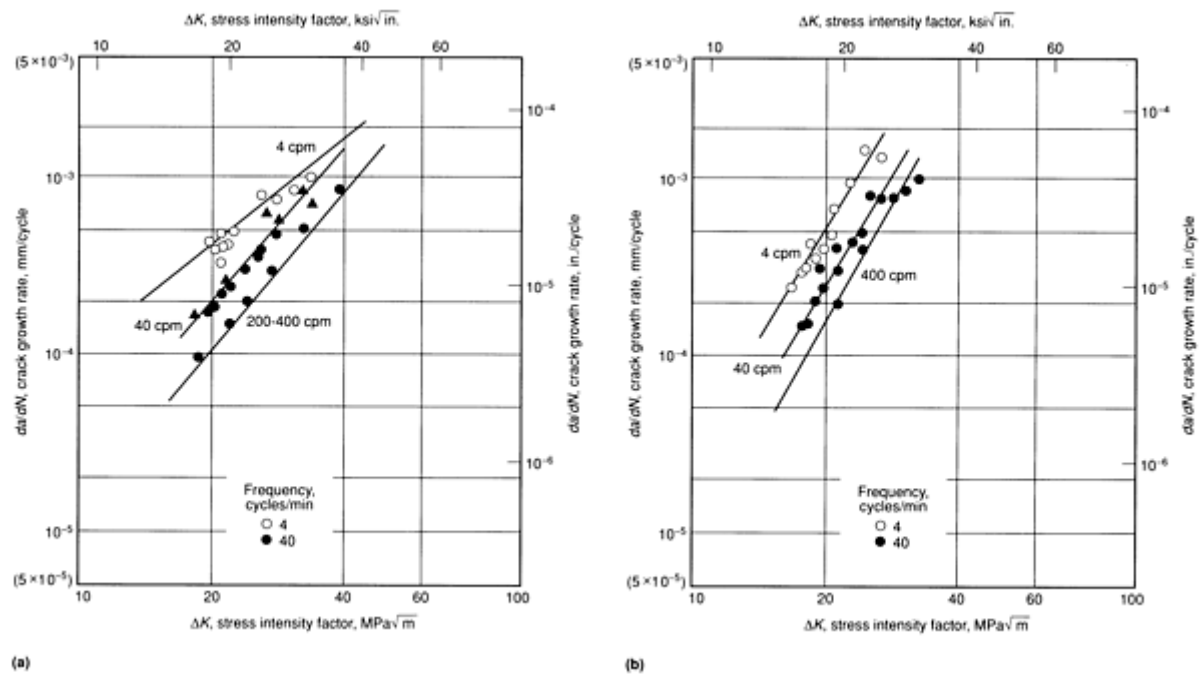

Fig. 56 Effect of cyclic frequency on fatigue crack growth rate. Variations in fatigue crack growth rate with cyclic frequency for specimens of $2\frac{1}{4}$ Cr-1Mo steel tested in air. Stress ratio was 0.05. (a) Tested at 510 °C (950 °F). (b) Tested at 595 °C (1100 °F). Source: Ref 85

The introduction of a holding period at the peak strain of each fatigue cycle reduces fatigue life as described in the section "Creep-Fatigue Interaction." From studies conducted on annealed 2.25Cr-1Mo steel in air (Ref 6, 81, 86), it is possible to conclude the following (Ref 30):

- Compressive hold periods are more damaging than tensile hold periods, and hold periods imposed on the tension-going side of the hysteresis loop are more damaging in terms of reduced cycle life than hold periods on the compression-going side
- Linear damage summation of fatigue and creep damage does not sum to a unique value

The fact that the damage sums are less than 1 indicates apparent creep-fatigue interaction, but because the values shown do not trend toward a unique value, the linear damage summation method is highly questionable for data extrapolation. The primary reason that the damage sums are less than 1 is that significant environmental interaction or corrosion fatigue occurs in air. This oxidation can substantially reduce the time for crack initiation in smooth bar tests, depending on waveform, and is not adequately accounted for by the simple linear damage summation of fatigue and creep damage fractions. Environmental interaction is discussed in the section "Factors Affecting Fatigue Strength" in this article.

Properties of Welds in $2\frac{1}{4}$ Cr-1Mo Steel. Welding is often required in the fabrication of pressure vessels, boilers, heat exchangers, and similar structures for use at elevated temperatures in power plants, refineries, chemical-processing plants, and similar applications. Therefore, in evaluating materials for these structures, it is important to consider the mechanical properties of welded joints.

In one investigation, the elevated-temperature tensile and creep-rupture properties of weldments in $2\frac{1}{4}$ Cr-1Mo steel were measured (Ref 87, 88). Specimens were cut from the weld metal and the base metal; other specimens had transverse welds. All specimens were tempered at 705 °C (1300 °F) before testing. In all these tests, the weld metal was stronger than either the base metal or the specimens containing transverse welds. Specimens with transverse welds invariably fractured in the base metal. The high strength of the weld metal relative to that of the base metal was attributed of

differences in microstructure. The base metal, which had been normalized and tempered, contained more ferrite and less bainite than the weld metal. In these tests, the base metal was the weakest part of the welded structure.

Elevated-Temperature Properties of Ferritic Steels

Thermal Expansion and Conductivity

Because of their higher thermal conductivity and lower thermal coefficient of expansion, ferritic steels may be more desirable than austenitic steels when thermal cycling occurs in service. Figures 57 and 58 indicate the thermal conductivity and expansion coefficient for carbon and low-alloy steels as a function of temperature.

Fig. 57 Thermal conductivity of carbon and low-alloy steels at various temperatures

Fig. 58 Coefficients of thermal expansion for carbon and low-alloy steels at various temperatures. These are not mean values of the coefficient over a range of temperatures.

Effect of Neutron Irradiation on Properties of Steels *

R.L. Klueh, Metals and Ceramics Division, Oak Ridge National Laboratory

Introduction

DAMAGE TO STEELS from neutron irradiation affects the properties of steels and is an important factor in the design of safe and economical components for fission and fusion reactors. Damage occurs when high-energy neutrons displace metal atoms from their normal lattice positions to form interstitials and vacancies. It is the disposition of these defects that influences properties during and after irradiation. In addition to the formation of vacancies and interstitials, transmutation reactions can also occur when neutrons are absorbed by the atoms of an irradiated alloy. These transmutation reactions produce new metal atoms and gas atoms of hydrogen and/or helium within the alloy matrix. Of these various transmutation by-products, transmutation helium is considered the most significant in exacerbating property changes.

The effects of damage caused by neutron irradiation include swelling (volume increase), irradiation hardening, and irradiation embrittlement (the influence of irradiation hardening on fracture toughness). These effects are primarily associated with high-energy (>0.1 MeV) neutrons. Consequently, irradiation damage from neutrons is of considerable importance in fast reactors, which produce a significant flux of high-energy neutrons during operation.

However, irradiation damage from neutrons is also a factor in commercial light-water reactors, even though neutrons in a light-water reactor are moderated to reduce their energy (most neutrons in the spectrum of these reactors are thermal neutrons with energies much less than 1 eV). Such reactors produce a small flux of high-energy neutrons, and until recently, these neutrons were the only ones considered to cause the irradiation effects observed in power reactors. However, as discussed in the section "Irradiation Embrittlement" in this article, recent observations have indicated that thermal neutrons can also cause irradiation effects. Therefore, material damage from neutron irradiation is important not only in fast reactors, such as the experimental Fast Flux Test Facility (FFTF) in Hanford, Washington, and the Super Phenix fast-breeder electric power reactor in France, but also in the many commercial light-water power reactors. In addition, the future of economically viable fusion reactors may also depend on the development of irradiation-resistant alloys.

This article discusses the effects of high-energy neutrons on steels, with particular emphasis on the steels listed in Table 1. For the pressure vessels of light-water reactors the manganese-molybdenum-nickel ferritic steels (ASTM A 302-B and A 533-B) are commonly used. These steels are quenched and tempered, which produces a tempered martensite and/or tempered bainite microstructure. Austenitic steels such as type 316 stainless steel are proposed for fusion reactors and are used in fast reactors for fuel cladding, ducts, and other structural components. These steels are used in either the solution-annealed or the 20% cold-worked condition. Special irradiation-resistant austenitic steels have been developed for these applications. An example of such a new steel is the prime candidate alloy (PCA) for fusion (Table 1). For both the fast-breeder reactor and fusion reactors, chromium-molybdenum ferritic are being considered. Of special interest are the 9Cr-1MoVNb and 12Cr-1MoVW steels; $2\frac{1}{4}$ Cr-1Mo steel is also considered for fusion reactors. These steels are used in a normalized and tempered condition, which gives a tempered martensite microstructure in the 9Cr-1MoVNb and 12Cr-1MoVW steels and a tempered bainite microstructure in the $2\frac{1}{4}$ Cr-1Mo steel.

Table 1 Typical compositions for steels of interest for nuclear reactor applications

Steel	Chemical composition, wt%										
	Cr	Ni	Mo	Mn	Si	C	V	Nb	W	Ti	N
Austenitic stainless steels											
316 stainless steel	18.0	13.0	2.5	2.0	0.8	0.05	0.05	0.05
PCA steel	14.0	16.0	2.5	1.7	0.4	0.05	0.25	...
Ferritic steels											
A302	0.1	0.2	0.5	1.3	...	0.2
A533	...	0.5	0.5	1.3	...	0.2
$2\frac{1}{4}$ Cr-1Mo	2.25	0.25	1.0	0.5	0.3	0.12

9Cr-1MoVNb	9.0	0.2	1.0	0.5	0.3	0.10	0.2	0.08	0.5	...	0.05
12Cr-1MoVW	12.0	0.5	1.0	0.5	0.4	0.20	0.3

Effect of Neutron Irradiation on Properties of Steels*

R.L. Klueh, Metals and Ceramics Division, Oak Ridge National Laboratory

Irradiation Damage Processes

The current understanding of neutron irradiation effects has been obtained from studies on materials irradiated in fission test reactors, such as the FFTF, the Experimental Breeder Reactor (EBR-II), and the High Flux Isotope Reactor (HFIR) (Ref 1). Irradiation is described in terms of the flux of neutrons striking the steel being irradiated, which is measured as the number of neutrons per square meter per second ($\text{n/m}^2 \cdot \text{s}$), and the fluence, which is the time-integrated flux in neutrons per square meter (n/m^2). A typical flux for a fast reactor is $\sim 5 \times 10^{19} \text{ n/m}^2 \cdot \text{s}$.

Displacement Damage. When a steel is irradiated in a high-energy neutron field, neutrons collide with atoms in the material and displace them from their lattice positions (Ref 2, 3). The first atom struck and displaced by a neutron is termed a primary knock-on atom. When this primary knock-on atom recoils from the impact, it collides with other atoms, which in turn recoil and collide with still other atoms. Therefore, an incoming neutron can produce a displacement cascade, by which a large number of atoms are displaced from lattice sites. The displaced atoms of a displacement cascade move into interstitial positions (termed interstitials) and leave behind a like number of vacant sites (vacancies).

This displacement of atoms by irradiation is described in terms of displacements per atom (dpa), which is a measure of the average number of times an atom is displaced from its lattice position. The dpa can be calculated from the neutron fluence received by the steel (Ref 2, 3). During 1 year of fast reactor operation, each atom in stainless steel is typically displaced more than 30 times (30 dpa/yr). For a light-water reactor, the displacement rate in steel is about 0.03 dpa/yr. For a fusion reactor, displacement rates of up to 60 dpa/yr might be expected.

The disposition of the defects--interstitials and vacancies--determines the effect of the atomic displacements on the properties of an irradiated material. Although the average number of atomic displacements is described by the dpa unit, only a fraction of these displacements produce damage and property effects. In general, most (typically 95 to 99%) of the displaced atoms from a displacement cascade recombine with a vacancy. This is because the interstitials and vacancies produced in a displacement cascade are near each other and have a strong likelihood of recombining.

Therefore, displacement damage from neutron irradiation occurs from only a small portion of the atomic displacements. The interstitials and vacancies from this portion of the displacements do not recombine but instead migrate to sinks, where they are absorbed or accumulate. Sinks include surfaces, grain boundaries, dislocations, and existing cavities.

This migration of defects can also result in the formation of defect clusters; those consisting of interstitials can evolve into dislocation loops, while vacancy clusters can develop into microvoids or cavities (Fig. 1). Solute clusters can also form under certain conditions.

Fig. 1 Cavities (indicated as the white rectangles and circles) formed in type 316 stainless steel irradiated to 60 dpa at 600 °C (1110 °F) in the HFIR. Courtesy of P.J. Maziasz, Oak Ridge National Laboratory

The type of cluster defect that forms depends on the irradiation temperature. Below about $0.35 T_m$ (where T_m is the melting point of the irradiated material in degrees kelvin), interstitials are mobile relative to vacancies, and the interstitials combine to form dislocation loops. This gives rise to an increase in strength and a decrease in ductility.

Vacancies become increasingly mobile above $0.35 T_m$, and a dislocation and cavity structure results (Fig. 1). This microstructure occurs because certain sinks have a bias and do not accept vacancies and interstitials equally (Ref 2, 3). If all sinks accepted both defects equally, the vacancies and interstitials would annihilate at a sink, and no swelling would result. However, within a grain, interstitials are accepted preferentially by dislocations. This leaves an excess of vacancies to be absorbed by cavities, giving rise to the observed swelling.

Finally, at high irradiation temperatures (greater than about $0.6 T_m$), defect clusters are unstable. That is, the high equilibrium vacancy concentration and rapid diffusion lead to vacancy-interstitial recombination, which thus reduces the number of defects and the effects of displacement damage on properties. However, at temperatures $> 0.5 T_m$, any transmutation helium produced during irradiation can lead to problems.

Cavities. Two types of cavities form during irradiation--bubbles and voids. Bubbles contain gas at a pressure greater than or equal to the surface tension pressure. Voids have internal gas pressure below the equilibrium pressure. The origin of gas in irradiated material is described in the section "Transmutation Helium" in this article.

Radiation-Induced Segregation. Because certain alloying elements can be preferentially associated with or rejected by vacancies or interstitials, such elements can be transported to or from sinks when the defects migrate. This radiation-induced segregation can cause detrimental effects and must be considered when developing alloys for irradiation resistance (Ref 2, 3).

Transmutation Helium. In addition to displacement damage, a neutron can be absorbed by an atom of the irradiated alloy, resulting in a transmutation reaction that produces a new metal atom and hydrogen and/or helium gas atoms within the alloy being irradiated. Indications are that small amounts of new metal atoms have little effect on properties. Hydrogen will have little effect on properties because, at the operating temperatures of most reactors (250 to 550 °C, or 480 to 1020 °F), it should readily diffuse from the alloy. However, any helium produced can affect the properties; it is relatively insoluble in metals and will therefore be incorporated into the bubbles or voids that can form within the matrix and on grain boundaries and precipitate interfaces.

The displacement damage formed in fusion and fission reactors is similar, and fusion damage can be simulated by fission reactor irradiations. However, the much higher energy of the neutrons (up to 14 MeV) produced in a fusion reactor will lead to much more transmutation helium than occurs in most fission irradiations. Such a simultaneous development of displacement damage and helium can affect both the swelling behavior and the mechanical properties. Much recent research has been directed at determining the effect of helium on the properties of irradiated candidate structural alloys and on developing alloys that will withstand these effects (Ref 3).

Effect of Neutron Irradiation on Properties of Steels*

R.L. Klueh, Metals and Ceramics Division, Oak Ridge National Laboratory

Void Swelling

As mentioned earlier in the section "Displacement Damage" in this article, the bias of dislocations for interstitials causes an excess of vacancies to agglomerate at cavities (Fig. 1), which thus causes a volume increase or swelling of the irradiated alloy (bias-driven void swelling). Void swelling (measured as $\Delta V/V$, where ΔV is the change in volume of the irradiated material and V is the original volume) of several tens of percent is observed in some stainless steels. Large amounts of swelling cannot be tolerated in a reactor component, and considerable effort has been directed toward the development of swelling-resistant alloys for use in fast-breeder and fusion reactors. Void swelling is unimportant for light-water power reactors because of the low flux of high-energy neutrons in the neutron spectrum of such reactors.

Swelling in Austenitic Stainless Steels. Irradiations to fluences that produce displacement damage greater than 100 dpa have been conducted on types 304 and 316 stainless steel, and the swelling can be described as a function of temperature and fluence (Ref 2, 3), as illustrated in Fig. 2. For constant fluence, a peak swelling temperature is observed. At a constant temperature, there is an incubation time, after which swelling develops slowly with a power-law dependence on fluence. This transient regime is eventually replaced by a rapid-swelling regime characterized by a linear dependence (steady-state swelling) on fluence. Swelling in the steady-state regime for austenitic steels occurs at approximately 1%/dpa; the steady-state rate is essentially independent of composition and fabrication variables and is a weak function of temperature, irradiation rate, and stress (Ref 4, 5).

Fig. 2 Effect of temperature and neutron fluence on the swelling behavior of type 316 stainless steel irradiated in a fast reactor (EBR-II). Source: Ref 3

The high rate of swelling in the steady-state regime ($\sim 1\%/dpa$) suggested that the structural lifetime could be increased only by extending the transient regime (Ref 4, 5). Voids nucleate during the transient period, while their growth and coalescence occur during steady state. Void nucleation is aided by small amounts of dissolved gases (oxygen and nitrogen) or gases formed by transmutation reactions (helium). Gas can combine with irradiation-induced vacancies to

form bubbles. These bubbles collect vacancies until a critical radius for a void is reached, after which growth is bias driven. If the conversion from bubbles to voids can be inhibited, the transient stage can be extended, and swelling resistance is improved.

Although void swelling occurs because of the slight bias of dislocations as sinks for interstitials, a very high dislocation density can provide sufficient sinks for both vacancies and interstitials, where they can recombine and annihilate. This information has led to the use of 20%-cold-worked type 316 stainless steel for fast-breeder reactor fuel cladding.

Small amounts of titanium were found to extend the transient regime (Ref 6). Titanium was thought to getter oxygen and other dissolved gases and thus reduce the nucleation rate, which was delayed until small amounts of transmutation helium could aid nucleation. The addition of titanium and niobium to form carbides and phosphorus to form phosphides has a similar effect on transient swelling (Ref 4). In this case, the fine dispersions of stable precipitate particles trap helium at their interfaces, forming a high density of small bubbles of these locations. Because the irradiation-produced vacancies are collected by a larger number of cavities, the formation of the critical radius for void growth is delayed, and the transient regime is extended. The high density of cavities can also become the dominant sink for both vacancies and interstitials and therefore sites for recombination. Such alloying techniques have been applied in the breeder reactor and fusion reactor alloy development programs in an attempt to develop irradiation-resistant stainless steels, such as the PCA steel for fusion (Table 1).

In a fusion reactor, the large amounts of helium generated simultaneously with displacement damage will give rise to irradiation effects different from those observed in a breeder reactor. The information available for large helium concentrations at relevant damage rates is from comparisons of the behavior of type 316 stainless steel irradiated in fast reactors, such as the EBR-II, and in a mixed-spectrum reactor, such as the HFIR. In a mixed-spectrum reactor, the neutron spectrum contains both thermal and fast neutrons. When a nickel-containing steel is irradiated in the HFIR, the thermal neutrons react with ^{58}Ni to form helium, while the fast neutrons produce displacement damage just as they do in a fast reactor. Natural nickel contains approximately 68% ^{58}Ni .

Recent evidence indicates that increasing the He:dpa ratios from approximately 0.5 (EBR-II) to approximately 60 (HFIR) (the He concentration is in atomic parts per million, appm) may shorten or extend the transition regime, depending on the heat chemistry and the thermomechanical treatment (Ref 4). An extended transition regime is associated with a high density of bubbles, the inhibition of radiation-induced segregation, and the delayed conversion of bubbles to voids. For 20%-cold-worked type 316 stainless steel irradiated in the HFIR, helium is trapped on the high density of dislocations, leading to the nucleation of a high density of bubbles. Because of the large number of small bubbles present, they become the dominant sinks for both vacancies and interstitials, and swelling is inhibited. In solution-annealed steel, the opposite occurs. Helium is not effectively trapped, and bubble nucleation occurs on a coarser scale than in cold-worked material. This accelerates the transition of cavities from bubbles to voids and leads to greater swelling than that observed in the absence of high helium concentrations.

The precipitation of fine titanium-rich carbides (designated as MC, where the M indicates the carbide contains more than one type of metal atom) in the PCA steel for fusion (Table 1) enhances bubble nucleation per increment of generated helium (Ref 4). As long as fine dispersions of MCs are preserved during irradiation, the association of fine MCs with helium bubbles hinders bubble coarsening by coalescence. The resulting high density of bubble/precipitate sinks also suppresses radiation-induced segregation and thus further enhances MC stability. This is illustrated in Fig. 3, which compares the swelling behavior and micro-structure of cold-worked type 316 stainless steel and PCA steel. The low-swelling PCA steel contains a high density of small bubbles, compared to the large voids in the stainless steel. Helium-enhanced MC stability and suppressed radiation-induced segregation are essential in extending the transient regime of swelling for fusion compared to fast-breeder reactor irradiation. The performance of PCA steel illustrated in Fig. 3 is for an He:dpa ratio of approximately 60, while the value for a fusion reactor is expected to be about 10 to 12. It still must be determined whether the metal carbide will remain stable under fusion reactor conditions.

(a) Cavity volume swelling versus neutron fluence. (b) Microstructure of 316 stainless steel after about 43 dpa. (c) Microstructure of the PCA steel after about 43 dpa. Source: Ref 4

Swelling in Ferritic Steels. When chromium-molybdenum ferritic steels such as $2\frac{1}{4}\text{Cr-1Mo}$, 9Cr-1MoVNb, and 12Cr-1MoVW (Table 1) were irradiated in fast reactors to neutron fluences of $17.6 \times 10^{26} \text{ n/m}^2$ and a displacement-damage level of up to 80 dpa (helium concentrations <10 appm) at 300 to 600 °C (570 to 1110 °F), these steels swelled much less than austenitic stainless steels exposed to similar conditions (Ref 7, 8, 9). However, a significant amount of irradiation-induced precipitation occurred during these irradiations, and the subsequent influence of this precipitation on strength may prove to be the most significant effect for these steels (Ref 7, 8, 9).

As discussed above, the effects of simultaneous displacement damage and transmutation helium can be studied by irradiating nickel-containing alloys in HFIR. Standard 9Cr-1MoVNb steel contains approximately 0.2% Ni; 12Cr-1MoVW steel, approximately 0.5% Ni. These steels were irradiated in HFIR at 300 to 600 °C (570 to 1110 °F) to approximately 36 dpa to produce about 30 and 100 appm of helium for the 9Cr and 12Cr steels, respectively (Ref 9). Considerably more swelling was observed when helium was present than when irradiated in fast reactors to much higher damage levels with little helium present. For both steels, swelling was a maximum after irradiation at 400 °C (750 °F). Irradiation at 300, 500, and 600 °C (570, 930, and 1110 °F) resulted in some cavity formation, but negligible swelling. After irradiation at 300 and 400 °C (570 and 750 °F), the cavities were homogeneously distributed in the matrix. Irradiation at 500 and 600 °C (930 and 1110 °F) resulted in small bubbles at lath boundaries, prior-austenite grain boundaries, and dislocations. These were concluded to the helium-filled bubbles because of their small, uniform size and because they formed preferentially on structural defects. When compared to results in fast reactors, where no helium was produced, the HFIR results indicated that helium assists the nucleation of cavities (Ref 9).

To further study the effect of helium on swelling, 9Cr-1MoVNb and 12Cr-1MoVW steels doped with 2% Ni were irradiated in the HFIR. Examination of 9Cr-1MoVNb steel irradiated to 38 dpa to produce over 400 appm of helium indicated that the helium caused larger amounts of void and bubble formation over the range of 300 to 600 °C (570 to 1110 °F) than occurred during fast reactor irradiation (>10 appm He) (Ref 9). Furthermore, significantly greater amounts of precipitation occurred at 400 and 500 °C (750 and 930 °F) under conditions of increased void formation. It appeared that these precipitate changes were the result of irradiation-induced solute segregation, in which the migration of vacancies and helium to cavity surfaces is accompanied by the preferential migration of solute atoms away from these sites. This can result in irradiation-induced precipitate phases that are unstable under similar thermal conditions in the absence of neutron irradiation. Similar changes were noted for the 12Cr-1MoVW steel (Ref 9).

Effect of Neutron Irradiation on Properties of Steels*

R.L. Klueh, Metals and Ceramics Division, Oak Ridge National Laboratory

Mechanical Properties

Although ferritic steels are more resistant to swelling than austenitic steels, irradiation may have a more critical effect on the mechanical properties of ferritic steels. In particular, the effect of irradiation on fracture behavior is of crucial importance in light-water reactors and may limit the use of ferritic steels in fusion reactors. As noted above, low-temperature irradiation can result in the formation of dislocation loops, solute clusters, vacancy clusters, precipitates, and microvoids. This microstructural alteration causes most of the changes in mechanical properties. Transmutation helium can also affect mechanical properties.

Low-Temperature Tensile Behavior. An example of the effect of fast reactor irradiation on the strength of a ferritic steel is shown in Fig. 4 for 9Cr-1MoVNb steel irradiated in the EBR-II at 390 to 550 °C (735 to 1020 °F) and tested at the irradiation temperature. An increase in the yield stress is observed for irradiation up to about 425 °C (800 °F). No hardening occurred at 450 °C (840 °F) and above. With increasing fluence below approximately 425 °C (800 °F), strength increases to a saturation level, after which it remains unchanged. Depending on the steel and the fluence, irradiation-enhanced softening is possible at temperatures above about 425 °C (800 °F) because of recovery and precipitate coarsening, which can be hastened by the irradiation. The change in the ultimate tensile strength is similar to that of the yield stress. Changes in ductility reflect the strength changes; an increase in strength results in a ductility decrease and vice versa. In general, adequate ductility is maintained for these irradiation conditions. Similar observations have been made for 12Cr-1MoVW (Ref 11) and $2\frac{1}{4}$ Cr-1Mo steels (Ref 12).

Fig. 4 0.2% yield stress and ultimate tensile strength of 9Cr-1MoVNb steel as a function of test temperature for irradiated specimens (12 dpa), as-heat-treated controls, and thermally aged controls. The test temperature equals the irradiation and aging temperatures; specimens were aged 5000 h, which corresponded to the time in-reactor. Source Ref 10

To determine the effect of helium, nickel-doped 9Cr-1MoVNb and 12Cr-1MoVW steel tensile specimens were irradiated in the HFIR (Ref 13). The results were compared with results for undoped steels irradiated similarly and undoped and doped specimens irradiated in the EBR-II, in which little helium was generated. At 300 and 400 °C (570 and 750 °F), results indicated that the transmutation helium caused an increase in strength in addition to that caused by the displacement damage. No helium effect was apparent on specimens irradiated at 500 °C (930 °F).

A qualitatively similar behavior is observed when austenitic stainless steels are irradiated in the EBR-II (little helium). For type 316 stainless steel, both solution-annealed (Ref 14) and 20%-cold-worked (Ref 15) steels have been investigated in some detail. An attempt has been made to model the behavior observed in the EBR-II in terms of the defects produced during irradiation (Ref 16). Only minor differences were observed between stainless steels irradiated in the EBR-II and the HFIR up to approximately 600 °C (1110 °F), indicating that helium had little effect on tensile behavior under these conditions (Ref 17).

Elevated-Temperature Tensile Behavior--Helium Embrittlement. For elevated temperatures, displacement damage is no longer stable, and flow properties are basically unaffected by irradiation (Fig. 4). However, in certain irradiated alloys containing helium, the strength decreases upon irradiation at elevated temperatures, but the ductility also decreases (Ref 18). Total elongation measured in a tensile test drops to only a few tenths of a percent. Although a temperature of approximately $0.5 T_m$ is often associated with helium embrittlement, the temperature will depend on the helium concentration and the tensile strain rate. As the helium concentration increases and/or the strain rate decreases, the temperature at which helium embrittlement occurs will decrease.

Elevated-temperature helium embrittlement is accompanied by intergranular fracture and is thought to be caused by helium on grain boundaries. For austenitic stainless steels, the effect can occur with the presence of only a few atomic parts per million of helium—even the small amounts formed during fast-reactor irradiation (Ref 18). Embrittlement is more severe for cold-worked than for solution-annealed material, although the effect generally appears at temperatures at which recrystallization or recovery of the cold-worked material occurs.

The large difference between the embrittlement of cold-worked and solution-annealed austenitic steels may indicate that some grain-boundary migration (by recrystallization or grain growth) during irradiation or testing may be necessary to obtain the extremely low elongations found in austenitic stainless steels. The difference between the cold-worked and solution-annealed type 316 stainless steels might be explained by grain boundaries collecting helium during recrystallization of the cold-worked structure.

Such embrittlement could impose an upper temperature limit on the use of austenitic steels. Again, alloying with titanium can improve resistance to embrittlement. The improvement is due to bubble refinement when helium is trapped on MC particles, as shown in Fig. 5 for PCA steel. The PCA-A1 was in a solution-annealed condition with no MC particles (Fig. 5c). The PCA-B3 was aged at 800 °C (1470 °F) prior to 25% cold working. When the helium was trapped in the fine bubbles formed on the metal carbides (Fig. 5b), a relatively small change in ductility occurred upon irradiation at 600 °C (1110 °F) to approximately 22 dpa and 1750 appm of helium (Ref 17). Without helium trapping (Fig. 5c), the helium collected at grain boundaries, and a much larger decrease in ductility occurred. It should be noted, however, that irradiation to higher fluences will be required to determine if this resistance to helium embrittlement continues.

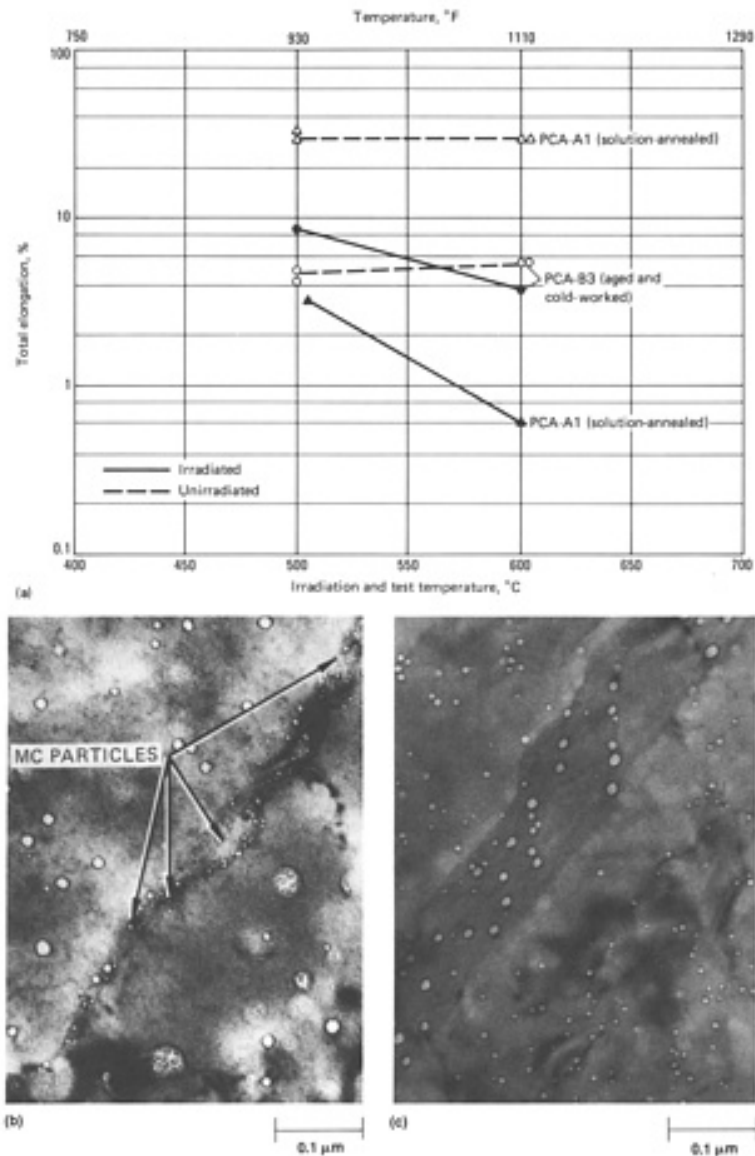

Fig. 5 Tensile ductility (a) of solution-annealed PCA steel and aged and cold-worked PCA steel. Irradiation caused a large decrease in the ductility of the solution-annealed PCA steel but not the cold-worked steel. This difference was correlated with fine bubbles on the MC precipitates that were present in the aged and cold-worked steel (b) but not in the solution-annealed steel (c). Source: Ref 17

All indications are that the martensitic steels, such as 9Cr-1MoVNb and 12Cr-1MoVW, are much more immune to helium embrittlement than the austenitic steels (Ref 19). The reasons for such resistance are not completely understood. Immunity is not inherent in the body-centered cubic (bcc) crystal structure (compared to the face-centered cubic structure), because helium embrittlement occurs in vanadium and niobium alloys. It appears likely that the resistance to helium embrittlement is related to the martensitic microstructure.

In the normalized condition, martensite has a fine lath structure containing a high density of dislocations. After tempering, a ferrite matrix containing a high density of carbide particles and a lower dislocation density remains. However, the distinctive lath structure is still evident; long laths, separated mostly by low-angle boundaries, are grouped in packets. The packets and some laths are separated by high-angle boundaries. Prior-austenite grain boundaries are also present. This type of fine microstructure should allow the partitioning of helium atoms to the various boundaries, including the precipitate boundaries. Such a wide distribution of helium should effectively keep the helium concentration on a given high-angle grain boundary relatively low and should reduce the probability of intergranular failure (an intergranular failure is expected to propagate along high-angle boundaries).

If the above conclusions are correct, then a much larger effect of helium would be expected on pure iron or on a steel with a polygonal ferrite structure (as opposed to a martensitic or bainitic microstructure). The many collection sites available in martensite are not present in pure iron, and the grain boundaries in such precipitate-free microstructures are more mobile at elevated temperatures. Indeed, this may explain the reduced ductility values observed on steels with a ferrite microstructure. For example, the total elongation of types 405 and 430 ferritic stainless steels containing 40 appm of helium decreased from 52 to 33% and 89 to 48%, respectively, when tested at 700 °C (1290 °F) (Ref 20).

Irradiation Embrittlement. A Major concern for bcc ferritic steels involves the effect of irradiation on fracture toughness (Ref 21, 22). Irradiation can cause large increases in the ductile-to-brittle transition temperature (DBTT) and decreases in the upper-shelf energy (USE), as measured by Charpy V-notch specimens. Even if the DBTT of the unirradiated steel is below room temperature, it can be well above room temperature after irradiation.

Irradiation embrittlement is related to the radiation-produced dislocation loops that form below $0.35 T_m$; irradiation-induced precipitates can also have an effect. Loops are barriers to dislocation motion and give rise to the strengthening discussed above. The relationship of this increase in flow stress to irradiation embrittlement is shown schematically in Fig. 6. Figure 6 shows how irradiation has shifted the flow stress upward. Under the assumption that the intersection of the fracture stress curve and the flow stress curve is the DBTT for the unflawed condition, the increase in flow stress is seen to cause a shift in the DBTT.

Fig. 6 Schematic of suggested mechanism by which a strength increase due to irradiation causes an upward shift in the DBTT. Source: Ref 21

Although swelling and the other aspects of radiation damage do not play a role in light-water power reactors, irradiation embrittlement has been a major concern. Low-alloy pressure vessel steels specified by ASTM A 302-B and A 533-B are commonly used for this application.

Shifts in DBTT of over 200 °C (360 °F) have been observed in A 302-B irradiated at less than 232 °C (450 °F) to fluences of approximately 1×10^{24} n/m², which is less than 0.1 dpa (Fig. 7). Because displacement damage can be eliminated by annealing, the magnitude of the DBTT shift for a given fluence generally decreases with temperature. For a given temperature, embrittlement is rapid with increasing fluence at low fluence. A marked decrease in rate of embrittlement (as measured by the upward shift in DBTT) is then observed, and the rate appears to go to zero with increasing fluence (that is, saturation) (Fig. 7).

Fig. 7 Effect of neutron fluence on the 41 J (30 ft · lbf) transition temperature in Charpy impact tests at temperatures below 232 °C (450 °F). Test specimen: 150 mm (6 in.) thick manganese-molybdenum steel (ASTM A 302, grade B). Source: Ref 21

Irradiation embrittlement of the pressure vessel steels exposed to fluences typical of light-water reactors is affected by heat-to-heat variations, microstructure, and residual element content (Ref 21). Of the residual elements, copper and phosphorus have the greatest effect. One proposed mechanism for the effect of copper is that it enhances the formation of dislocation loops that lead to hardening (Ref 21). The effect of phosphorus has been attributed to a mechanism similar to the role it plays in temper embrittlement. This effect manifests itself under these conditions because of radiation-enhanced diffusion (Ref 21). Postirradiation heat treatment can restore the DBTT of low-alloy pressure vessel steels (Ref 21).

Neutrons are moderated in light-water reactors to produce thermal neutrons, but a considerable flux of fast neutrons is still present. It is these neutrons with energies above about 1 MeV that are generally considered to produce the damage that causes the irradiation embrittlement (Ref 21). However, accelerated embrittlement was recently observed in surveillance specimens for the pressure vessel of the HFIR. These ASTM A 212-B steel specimens were irradiated at about 50 °C (120 °F) in a high thermal-to-fast-flux ratio position, where the measured property change was about an order of magnitude larger than that expected on the basis of the fast neutron fluence (Ref 23).

Although thermal neutrons do not possess sufficient energy to dislodge an atom from the matrix, thermal neutrons can cause damage indirectly through transmutation reactions. In particular, a reaction between a thermal neutron and ^{56}Fe to form ^{57}Fe causes an atom recoil, when a γ -ray is released. Displacement damage by this recoil can cause the embrittlement observed in the HFIR (Ref 24). Recoil from a reaction between a thermal neutron and boron to form an α -particle can also cause displacement damage. Damage from these transmutation reactions becomes important whenever the displacement-damage energy deposited by these reactions comes within an order of magnitude of that deposited by fast neutrons (Ref 24). The displacement damage produced by thermal neutrons is believed to be more efficient than that produced by fast neutrons in causing microstructural changes leading to embrittlement. This is because the displacement cascades from the recoil reactions are smaller than those for fast neutrons; consequently, less in-cascade recombination (loss) of vacancies and interstitials takes place for thermal neutrons. Recoil displacement are expected to be especially important at low temperatures, as is the case in the support structure of light-water reactors (Ref 24).

Irradiation embrittlement must also be considered in the development of ferritic steels for fast reactors and fusion reactors (Ref 22). The ferritic steels considered for use for fast-breeder reactors and fusion reactors are quite different from the low-alloy pressure vessel steels used for light-water reactors (Table 1). Furthermore, the types of fluences to which these steels will be exposed are considerably greater. While a light-water reactor steel will be irradiated to levels of the order of $1 \times 10^{24} \text{ n/m}^2$, which produces a displacement-damage level of less than 0.1 dpa, fluences of two to three orders of magnitude higher and damage levels exceeding 200 dpa are expected for fast-breeder and fusion reactors.

Charpy impact tests for the pressure vessel steels are generally conducted using standard Charpy V-notch specimens. Because of space limitations in most test reactors used for the fast-breeder and fusion reactor programs, miniature Charpy V-notch (half- and third-size) specimens are used (Ref 25). Results from comparisons of the different specimen sizes have shown that the smaller specimens exhibit behavior relatively similar to that of large specimens (that is, increase in DBTT and decrease in USE). However, the magnitude of the USE is greatly reduced, and the DBTT is lower (Ref 25).

Because of the appearance of a saturation in the shift in DBTT of the pressure vessel steels after an irradiation to approximately 2×10^{23} n/m² (Fig. 7), miniature specimens of 12Cr-1MoVW steel were irradiated at 300 °C (570 °F) to typical light-water reactor fluences in the University of Buffalo reactor (UBR) to 8.6×10^{23} n/m² (<0.1 dpa) and compared with similar specimens irradiated in the HFIR to approximately 8×10^{25} n/m² (4 to 9 dpa) (Fig. 8). After irradiation in the UBR, the DBTT increased by 36 °C (65 °F), and after irradiation in the HFIR, it increased by 164 °C (295 °F), indicating no saturation. Comparable decreases in the USE were also observed (Fig. 8).

Fig. 8 Shift in DBTT for 12Cr-1MoVW steel irradiated at 300 °C (570 °F) to fluence of 8.6×10^{23} and 8×10^{25} n/m². Source: Ref 26

Although the saturation observed for steels irradiated in light-water reactors did not apply to the HFIR, 9Cr-1MoVNb and 12Cr-1MoVW steels showed a saturation when irradiated in the EBR-II fast reactor (Ref 27). Above approximately 13 dpa, no further increase in the DBTT shift occurred when irradiated up to 26 dpa. However, when these steels were irradiated in the mixed neutron spectrum of the HFIR, the saturation observed in the EBR-II did not apply. A much larger shift in DBTT was observed (Ref 24). One possible explanation is that the helium generated the HFIR played a role.

Another unusual effect occurred when 12Cr-1MoVW was irradiated at 300 and 400 °C (570 and 750 °F) in the HFIR: The shift in DBTT at 400 °C (750 °F) was 217 °C (390 °F), but was only 164 °C (295 °F) after irradiation at 300 °C (570 °F) (Ref 26). The shift at 400 °C (750 °F) was also higher than that after irradiation at 55 °C (130 °F) (Ref 28). These observation were contrary to observations of pressure vessel steels, where the amount of shift generally decreased with increasing irradiation temperature. Further, the shift in DBTT is expected to be proportional to hardening as measured in a tensile test where the hardening decreases with increasing temperature. When 9Cr-1MoVNb and 12Cr-1MoVW steels were irradiated above 400 °C (750 °F), the magnitude of the shift again decreased, and above approximately 450 °C (840 °F) the shift became quite small (Ref 27, 29). All indications are, therefore, that the shift in DBTT for 12Cr-1MOVW steel goes through a maximum with irradiation temperature (Ref 26).

Such a maximum in DBTT shift may arise from the dislocation and precipitation structure that results from irradiation near 400 °C (750 °F) (Ref 9, 30). This structure could have a maximum influence near 400 °C (750 °F), because at lower temperatures, precipitate formation is inhibited by unfavorable kinetics, and at higher temperatures, precipitate coarsening causes softening. An effect of helium cannot be ruled out, because the maximum shift in DBTT with temperature relies on data obtained from irradiations in the HFIR. It was also found that swelling in 9Cr-1MoVNb and 12Cr-1MoVW steels was a maximum at 400 °C (750 °F) (Ref 9). Because of the design of fast reactors in which irradiation temperatures below approximately 390 °C (735 °F) are not possible, no tests can be made to determine a maximum for irradiations in such reactors.

Other Properties. Irradiation effects on properties such as thermal creep (Ref 31) and fatigue (Ref 32) have been investigated. Two interesting phenomena that may be important for fast fission reactors and fusion reactors are irradiation creep (Ref 33) and the effect of irradiation in intergranular stress-corrosion cracking (ISCC) (Ref 34).

Irradiation Creep. If a specimen stressed to a load less than that required to cause thermal creep is irradiated in a fast reactor, deformation (creep) occurs under certain experimental conditions (temperature, stress, fluence). One explanation for irradiation creep involves the preferential absorption of radiation-produced interstitials by dislocations properly oriented relative to the stress such that they can climb under the influence of the irradiation-produced interstitials (Ref 33).

Irradiation-assisted SCC is an intergranular SCC phenomenon that has occurred in the stainless steel neutron source holders, control blade absorber tubes (Fig. 9), and nuclear instrument tube holders of commercial boiling-water reactors. Irradiation-assisted SCC has also occurred in commercial pressurized-water reactors (Ref 32).

Fig. 9 Irradiation-assisted SCC of a stainless steel (Type 304) control blade absorber tube. 500×

Like the ISCC of stainless steels without any neutron irradiation, the irradiation-assisted SCC of stainless steels requires the presence of oxygenated high-temperature water. However, it is extremely important to note that irradiation-assisted SCC does not require the chromium depletion sensitization or high tensile stresses that are implicit in the ISCC of nonirradiated stainless steel components. There is some evidence that nonsensitized stainless steels become partially sensitized (that is, chromium depletion at the grain boundaries) during irradiation by the effect of radiation-induced segregation, thus reducing the resistance of the stainless steel to ISCC in aqueous environments (Ref 34). The mechanism of irradiation-assisted SCC appears to involve the simultaneous interaction of highly irradiated nonsensitized material with diffusion of impurities (sulfur, silicon, and phosphorus) to the grain boundaries, low stress (fabrication, irradiation creep), and high-temperature water with short-lived oxidizing species. In boiling-water reactors, no irradiation-assisted SCC has been observed at a neutron (>1 MeV) fluence below about 5×10^{20} n/cm² (see the article "Corrosion in the Nuclear Power Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). High tensile stresses are not necessary for irradiation-assisted SCC, and cracks may occur at lower stresses for higher fluences. However, high tensile stress can exacerbate the problem.

Introduction

CRITICAL STRUCTURAL COMPONENTS must be fabricated from steels that exhibit adequate low-temperature fracture toughness because of the serious consequences of failure due to brittle fracture. Codes used for the design of offshore structures specify low-temperature toughness requirements, and steel specifications that satisfy these requirements have been developed. The need for steels with higher fracture toughness and better weldability, as well as lower cost, has prompted major advancements in structural steel technology. These advancements are highlighted by the development of controlled-rolled and accelerated-cooled steels. This article reviews fracture resistance assessment procedures for welded joints and includes discussions on fatigue crack growth and fracture toughness. Fracture toughness requirements specified by different design codes are presented, and American Petroleum Institute (API), British Standards Institution (BSI), and American Society for Testing and Materials (ASTM) specifications for offshore structural steels are summarized, and applications of these specifications are discussed. This article also focuses on advances made in steel technology and the impact of these advances on the fracture toughness of steel.

Design and Failure Criteria

Three major factors contribute to service failure of steel structures:

- Brittle failure due to the presence of fabrication defects
- Fatigue crack development
- Crack development as a result of accidental damage

It is not practical or economical to fabricate defect-free structures. Although the use of appropriate inspection and quality control procedures can limit the size of defects, it cannot eliminate defects entirely. Proper fatigue design practices and in-service inspection can control the growth of fatigue cracks, however, complete elimination of small fatigue cracks is unrealistic, particularly for complex welded structures. Ductile failure due to growth of fatigue cracks to a large, plastic collapse critical size is a rare event, but it is still more common than brittle fracture, especially in structures subjected to the turbulent North Sea environment. Ductile failure in the absence of cracklike defects is experienced only in cases of accidental overloads that grossly exceed normal design stresses.

In addition to catastrophic failures of ships, tankers, offshore structures, pipelines, bridges, and vessels (Ref 1, 2, 3), numerous minor brittle failures of structures under construction or in service have resulted in delays and expensive repairs. To minimize the probability of these failures, the design of modern structures is based on the combined use of the methods of both classical design and structural integrity design. Structural integrity design is employed to prevent structural failure due to brittle fracture or premature fatigue cracking. Integrity design provides a tool for assessing fracture resistance by integrating stress analysis with evaluations of fabrication quality and the mechanical properties of the steel. The mechanical properties that are evaluated include fatigue crack growth, fracture toughness, and basic tensile properties (for example, yield strength and tensile strength).

Currently, all design guidelines, codes, or standards for critical applications emphasize fracture control procedures that provide for the evaluation of properties such as fracture toughness, weldability, and strength. Stringent steel qualification criteria have contributed to the development of low-cost structural steels possessing superior mechanical properties. These

structural steels combine desired properties such as higher strength, improved weldability, and higher fracture toughness in one product. These properties are vital in steels used for offshore structures because the inaccessibility of these structures makes in-service inspection and repair very difficult and extremely expensive.

Assessment of Fracture Resistance

The offshore industry has used several advanced fracture mechanics methodologies and tests to establish allowable final defect, a_f (Ref 4). These include crack tip opening displacement (CTOD), tests, and, to a lesser extent, crack growth resistance, J_R , and failure assessment diagram methods. The CTOD approach allows calculation of size of the allowable final defect, a_f , using the following expression for the ratio between the critical defect and the CTOD value (Ref 5):

$$\frac{a_f}{CTOD} = \frac{1}{2p(Y/E)[SCF(S/Y) + \alpha - 0.25]} \quad (\text{Eq 1})$$

where a_f is the half-length of a through-thickness rectilinear crack (for surface and buried cracks, and for crack geometries other than through-thickness rectilinear cracks, the equivalent through-thickness cracks, can be estimated by utilizing relationships available in fracture mechanics handbooks or from the literature (for example, Ref 6), Y/E is the ratio between the yield strength and the modulus of elasticity of the material, S/Y is the ratio between the nominal applied stress and the yield strength, SCF is the stress concentration factor, and α is the stress relief parameter, which equals 1.0 for no stress relief (that is, residual stress equals Y) and equals 0.0 for full stress relief (that is, no residual stress).

Ensuring against brittle fracture by specifying a blanket CTOD value is difficult without performing detailed fatigue life calculations. However, toughness specifications in terms of CTOD values are valuable when used in conjunction with fatigue crack growth rate data in the framework of fracture mechanics analysis; they can provide useful information on tolerable defects, remaining product life, and allowable loading conditions. Because of the complexity of CTOD testing (Ref 7), most design codes still rely on Charpy V-notch (CVN) energy and transition temperature concepts as the main fracture toughness acceptance criteria. The CVN impact test is performed following international standards such as ASTM A 370 or BSI 131.

Low-Temperature Properties of Structural Steels

Mamdouh M. Salama, Conoco Inc.

Fracture Toughness Requirements

Almost all design guidelines for critical structures specify a minimum fracture toughness requirement. This section summarizes toughness requirements given by three existing design guidelines used in the offshore industry. These guidelines have been developed by API, the United Kingdom Department of Energy (DEn), and Det Norske Veritas (DNV), a Norwegian ship classifier. The fracture toughness criteria used in these guidelines are based mainly on CVN impact energy and transition temperature criteria.

According to API RP 2A (Ref 8), underwater joints should meet notch toughness requirements as established by either the Naval Research Laboratory drop-weight test (ASTM E 208) or the CVN impact energy test. For the drop-weight test, the joints should be rated for no-break performance. The CVN test is performed on transverse test specimens. The minimum Charpy energy is specified as a function of the minimum yield strength of the steel (Table 1). The test temperature is specified as a function of the lowest anticipated service temperature (LAST) and the pipe diameter-to-thickness ratio, D/t :

$D/t^{(a)}$	Test temperature ^(b)		Condition of testpiece
	°C	°F	
<20	LAST - 10	LAST - 18	As-fabricated
20-30	LAST - 30	LAST - 54	Flat plate
>30	LAST - 20	LAST - 36	Flat plate

(a) D/t , diameter-to-thickness ratio.

(b) LAST, lowest anticipated service temperature

Table 1 Yield strength and impact energy guidelines for low-temperature structural steels

Specification	Minimum yield strength	Minimum Charpy V-notch impact energy	
		Average	Individual

			Transverse		Longitudinal		Transverse		Longitudinal	
	MPa	ksi	J	ft · lbf	J	ft · lbf	J	ft · lbf	J	ft · lbf
API RP 2A	<280	<40	20	15	13 ^(a)	9.8 ^(a)
	280-360	40-52	34	25	27 ^(a)	19.8 ^(a)
	>360	>52	48	35	41 ^(a)	29.8 ^(a)
United Kingdom DEn	$Y^{(b)}$	$Y^{(b)}$	0.10Y	0.10Y	0.07Y	0.07Y
DNV	$Y \leq 275$	$Y \leq 40$	18	13	27	20	14 ^(c)	9.8 ^(c)	20 ^(c)	15 ^(c)
	$Y > 275$	$Y > 40$	0.07 Y	0.07 Y	0.10 Y	0.10 Y	0.053 Y ^(c)	0.053 Y ^(c)	0.075 Y ^(c)	0.075 Y ^(c)

(a) Minimum individual impact energy = minimum average -7 J, or -5.2 ft · lbf.

(b) Y, minimum yield strength of the thinnest plate.

(c) Minimum individual CVN value = $0.75 \times$ (minimum required average value)

For a D/t less than 20, the Charpy specimen is machined from as-fabricated pipe, and the test temperature is 10 °C (18 °F) below LAST. On the other hand, for a higher D/t , testing is conducted on samples machined from flat plates. A lower temperature is specified for this test to account for possible toughness deterioration due to strains induced by forming (D/t of 20 is equivalent to 5% strain). No recommendations about the effect of plate thickness on toughness requirements are provided by the API specification.

The DEn specification (Ref 9) provides fracture toughness criteria for structures located in the North Sea. The toughness criteria depend on the minimum yield strength and thickness of the plate, and on the postweld heat treatment, stress concentration, and location of test specimens. The recommended minimum average CVN values of transverse specimens are listed in Table 1, and the recommended test temperatures are summarized in Table 2.

Table 2 Recommended CVN test temperatures according to United Kingdom Department of Energy specifications

Thickness, t		Test location	Test Temperature							
			As-welded				Postweld heat treatment			
			Highly stressed		Others		Highly stressed		Others	
mm	in.		°C	°F	°C	°F	°C	°F	°C	°F

$t \leq 20$	$t \leq \frac{25}{32}$	Subsurface	-20	-5	-20	-5	-20	-5	-10	15
$20 < t \leq 100$	$\frac{25}{32} < t \leq 4$	Subsurface	-40	-40	-30	-20	-30	-20	-20	-5
$40 < t \leq 100$	$1\frac{9}{16} < t \leq 4$	Mid-thickness	-30	-20	-20	-5	-20	-5	-20	-5

The DNV standard (Ref 10) provides fracture toughness requirements using both CVN and CTOD approaches. The recommended average minimum energy level depends on the yield strength as given in Table 1. Table 3 lists the recommended impact-testing temperature in terms of the design temperature, T_D , where T_D is defined as 5 °C (9 °F) below the most probable lowest monthly mean temperature. The DNV specifications include minimum CTOD value requirements for weld procedure qualifications for plates 50 mm (2 in.) and greater in thickness. The requirements at the minimum design temperature are 0.35 mm (0.014 in.) for as-welded or local postweld heat-treated conditions, and 0.25 mm (0.010 in.) after furnace postweld heat treatment.

Table 3 Recommended CVN test temperature according to DNV specifications

Thickness, t		Test temperature ^(a)					
		Special steel		Primary steel		Secondary steel	
mm	in.	°C	°F	°C	°F	°C	°F
$t \leq 12.5$	$t \leq \frac{1}{2}$	T_D	T_D	T_D	T_D
$12.5 < t \leq 25.5$	$\frac{1}{2} < t \leq 1$	$T_D - 20$	$T_D - 36$	T_D	T_D
$25.5 < t \leq 50$	$1 < t \leq 2$	$T_D - 40$	$T_D - 72$	$T_D - 20$	$T_D - 36$	T_D	T_D
$t > 50$	$t > 2$	$T_D - 40$	$T_D - 72$	$T_D - 40$	$T_D - 72$	$T_D - 20$	$T_D - 36$

(a) T_D , design temperature

There are some differences in toughness requirements among the design codes. Also, requirements continue to change with new issues of each code as more data become available. Table 4 highlights the importance of low-temperature toughness requirements for offshore structural steels by comparing the toughness requirements for two cases using the different codes. For thicker plates and for structures used in more severe environments such as the Arctic, higher fracture toughness values are required.

Table 4 Low-temperature fracture toughness requirements for 50 mm (2 in.) thick plate used in offshore structures

Structure location	Minimum water temperature		Specification	Minimum yield strength		Minimum individual CVN impact energy		Temperature

Fatigue Crack Growth in Structural Steel

Steel structures generally include complex welded joints that have large local stress concentrations and that are subject to fatigue loadings induced by environmental forces. This, in addition to fabrication defects that are often present in welded structures, will result in the early initiation of fatigue cracks. Eventually the crack grows to a size at which failure may occur. Therefore, the fatigue life of welded components can be estimated by integrating an appropriate crack growth equation such as Paris law between the allowable initial defect, a_i , and the final defect at which failure occurs, a_f . The size of the final defect depends on the fracture toughness of the material and the applied stress.

The Paris equation (Eq 2) is bounded by the threshold value, ΔK_o , and the critical value, K_{max} , which is a measure of the fracture toughness as shown in Fig. 1. The crack growth equation provides a relationship between the crack growth rate, da/dN , and the stress intensity factor range, ΔK in the following form:

$$\frac{da}{dN} = C(\Delta K)^m \quad (\text{Eq 2})$$

The stress intensity factor range, ΔK , is defined by:

$$\Delta K = \Delta S F \sqrt{pa} \quad (\text{Eq 3})$$

where ΔS is the cyclic stress range, F is a correction factor dependent on component and crack geometries, and a is the half-length of a through-thickness rectilinear crack.

Fig. 1 Idealized fatigue crack growth model

(Ref 13). These values predict crack growth rates that are about one order of magnitude higher than crack growth rates calculated using the values recommended in BS PD6493. Fatigue lives are therefore reduced by one order of magnitude due to the interactive effect of crack size.

The crack growth parameters C and m are experimentally determined constants that depend on the material, loading condition, and environment. Reference 6 provides a C value of 3×10^{-13} and an m value of 3, in units of N (load) and mm (length), for ferritic steels with yield strengths up to 600 MPa (87 ksi). These values are based on the upper limit of air fatigue data shown in Fig. 2 for a variety of weld metals and heat-affected zone (HAZ) microstructures (Ref 11). Since the development of these data, extensive fatigue crack growth data have been developed for offshore structural steels such as BS 4360 grade 50D. Figure 3 presents crack growth data for this steel in both an air environment and in free corrosion and cathodic protection (CP) conditions in seawater. The CP levels were between -800 and -1100 mV (with respect to a silver/silver chloride reference electrode). Figure 3 was developed using data from research done exclusively on rectangular through-thickness notched parent steel specimens (no weld metal or HAZ data are included) (Ref 12). The test frequency varied between 0.1 and 1.0 Hz, the temperature between 5 and 20 °C (40 and 70 °F) and the stress ratio, R , between 0.0 and 0.5. Based on these data, a C value of 2.3×10^{-12} and an m value of 3 (in units of N and mm) have been suggested

Fig. 2 Fatigue crack growth in the weld metal and heat-affected zones of carbon-manganese steel base plates in an air environment

Fig. 3 Fatigue crack growth of BS 4360 grade 50D steel in air and in free corrosion and cathodic protection conditions in seawater

The Paris crack growth equation is generally valid within the ΔK range of 300 to 1800 $\text{MPa} \sqrt{\text{mm}}$ (9 to 52 $\text{ksi} \sqrt{\text{in}}$). Values of K below about 300 $\text{MPa} \sqrt{\text{mm}}$ (9 $\text{ksi} \sqrt{\text{in}}$) fall in the threshold range where crack propagation does not occur, and values above about 1800 $\text{MPa} \sqrt{\text{mm}}$ (52 $\text{ksi} \sqrt{\text{in}}$) fall in the range where the static mode of fracture occurs as the fracture toughness limit of the material is approached.

The following relationship between ΔK_o and the applied stress ratio, R , is provided in BS PD6493:

$$\Delta k_o = 190 - 144R \text{ MPa} \sqrt{\text{mm}} \quad (\text{Eq 4})$$

In Eq 4, ΔK_o depends on R . The Paris equation (Eq 2) does not depend on R . The relationship presented in Eq 4 provides the lower bound to all published threshold data for grade 50D steel in air and seawater (Ref 9). It has been suggested that other data for similar steels and for austenitic steels lie below the PD6493 line (Ref 10). Including these data, the following relationship, based on a 97.7% probability of survival for the data in Fig. 4, has been recommended (Ref 10):

$$\Delta k_o = 170 - 214R \text{ MPa}\sqrt{\text{mm}} \text{ for } 0 \leq R < 0.5 = 63 \text{ MPa}\sqrt{\text{mm}} \text{ for } R \geq 0.5 \quad (\text{Eq 5})$$

Low-Temperature Properties of Structural Steels

Mamdouh M. Salama, Conoco Inc.

Steel Specifications

Structural steel specifications are generally based on the appropriate national or industry standards such as ASTM, API, BSI, and so on. In most cases, standards provide mainly basic requirements such as limits on chemical composition and tensile properties. During the mid-1960s, several in-service and structural fabrication problems in Gulf of Mexico offshore structures were encountered. These problems indicated that common pipes such as API 5L B and structural steels such as ASTM A 7 and ASTM A 36 do not always meet the design or service needs of the offshore industry (Ref 3).

Failure analysis studies on several salvaged structures have shown that low notch toughness, laminations in the steel, lamellar tearing, and poor weldability were major contributors to the failures. These results made offshore operators and certifying authorities cognizant of the need for more restrictive standards to ensure that the steels used for offshore applications are of high quality and satisfy strict fracture toughness and weldability requirements. Therefore, standards such as API 2H, 2Y, and 2W (Ref 14, 15, 16) were developed. The types of structural steels that are addressed in these standards include killed fine-grain normalized, controlled-rolled, and quenched and tempered steels, as well as controlled-rolled accelerated-cooled (referred to as thermomechanical control process, or TMCP), steel. In addition to the above API grades, special grades from general standards such as ASTM and BSI are also specified for offshore structures. Table 5 summarizes the chemical composition and mechanical properties of some offshore structural steels. There are several differences among these specifications in the details they provide regarding limitations on steelmaking, chemical composition, mechanical properties, and quality.

Tables 6 and 7 compare BSI and API specifications for tensile strength and toughness properties of similar grades of steel. In addition to the differences in toughness values, there are differences in how each specification handles the effect of thickness on the yield strength. Furthermore, API 2W and 2Y provide not only minimum yield and tensile strength limits, but also an upper limit on the yield strength. A limit on the maximum yield strength is very important to ensure a reasonable match between the strength of the weld metal and the base plate. In general, it is desirable to ensure that the weld metal strength is higher than the steel strength.

(a) API CVN tests use transverse specimens.

(b) API provides supplement S-7 for CVN tests using specimens uniformly strained 5% and aged at 250 °C (480 °F) for 1 h.

(c) S-2 supplementary requirement

In addition to the CVN toughness requirements in Table 7, API provides two supplements using different toughness criteria. The first supplement is for toughness based on crack tip opening displacement tests of weld HAZ. Tests are performed in accordance with Section 3 of API RP 2Z (Ref 18); the heat input is 1.5 to 5 kJ/mm (38 to 125 kJ/in.), and the preheat is 100 to 250 °C (210 to 480 °F). For thicknesses up to and including 75 mm (3 in.), the required CTOD value is 0.25 mm (0.010 in.) at -10 °C (15 °F). For thicknesses greater than 75 mm (3 in.), the required CTOD value is 0.38 mm (0.015 in.) at -10 °C (15 °F). The second supplement is for toughness of plates using the drop-weight test. The test is done in accordance with ASTM E 208 using P-3 specimens. The acceptable criterion is no-break performance at -35 °C (-30 °F).

Although standards for offshore structural steels are generally more restrictive than those used by other industries, they provide only minimum requirements for tensile properties, fracture toughness properties, control of chemical composition, and dimensional tolerances. Therefore, offshore operators often include additional requirements in the steel purchase specifications. These specifications generally include additional limitations on chemical composition along with requirements for higher toughness, a weldability evaluation, reduced tolerances, and an increased frequency of testing. Table 8 compares the chemical compositions of typical offshore structural steels and the composition allowed by the API 2H (Ref 14). In the typical steels, limits are imposed on more elements, and the maximum limits of carbon, sulfur

phosphorus, and carbon equivalent are reduced. These restrictions are intended to ensure improved toughness and weldability.

Table 8 API composition specification (product analysis) for offshore low-temperature structural steels compared with typical United States and foreign specifications

Low-Temperature Properties of Structural Steels

Mamdouh M. Salama, Conoco Inc.

Advances in Steel Technology

Many significant advances in steelmaking processes have been made by steel companies to meet the demand for high-quality lower-cost structural steels with higher strength, improved weldability, and increased fracture toughness. These advances include the close monitoring of the supply of desulfurized iron in the blast furnace, the widespread use of continuous casting of thick slab for rolling to plate, the introduction of vacuum arc degassing, vacuum degassing, and argon stirring and injection techniques, along with almost exclusive use of basic oxygen process steelmaking (Ref 19). These advances in the steelmaking process have resulted in major improvements in structural steels, including significant control of alloying elements (for example, carbon, manganese, niobium, vanadium, and aluminum), major reductions in impurities (for example, sulfur, phosphorus, and nitrogen), and improved uniformity of composition and properties. Recent advances in computer control and rolling capacity have allowed the development of a new class of high-strength low-alloy steels, namely TMCP steels. The TMCP involves both controlled rolling and controlled (accelerated) cooling to produce steels with a very fine grain size (ASTM 10 to 12). The main aim of TMCP is to increase strength and fracture toughness and improve weldability by reducing the carbon equivalent and controlling the chemical composition (additional information is available in the article "Weldability of Steels" in this Volume). The API 2W specification (Ref 16) covers TMCP steel plates with minimum yield strengths between 290 and 415 MPa (42 and 60 ksi).

Strength in TMCP steels is maximized by reducing the ferrite grain size and increasing the volume fraction of the second phase. Accelerated cooling is used to achieve these effects. The influence of cooling rate on strength and toughness is shown in Fig. 5. A variation in cooling rate can be expected between surface and mid-thickness regions of thick plates. The addition of small amounts of niobium is very effective in strengthening the steel without affecting toughness (Fig. 6). However, the addition of more than 0.04% Nb is not desirable because it can cause a reduction in toughness, particularly in the subcritically reheated grain-coarsened heat-affected zone.

Fracture Toughness Characteristics of Structural Steels

Fracture toughness of steel has improved greatly as a result of advances in steel technology. Figure 7 compares CVN transition curves of old and new steels using transverse subsurface specimens. Steel A is a 60 mm ($2\frac{3}{8}$ in.) carbon-manganese steel that was used in 1975. It has a carbon level of 0.21%. Steel B is a modern 70 mm ($2\frac{3}{4}$ in.) thick normalized carbon-manganese steel with a carbon level of 0.114% and some microalloying (0.29% Ni, 0.025% Nb, and 0.022% Cu). Steel C is a modern 50 mm (2 in.) thick controlled-rolled and accelerated-cooled TMCP steel with a carbon level of 0.11% and some microalloying (0.23% Ni, 0.03% Nb, and 0.24% Cu). The yield strengths of steels A, B, and C are 355, 369, and 506 MPa (51, 54, and 73 ksi), respectively. Figure 7 shows the improved fracture toughness of modern steels as indicated by a decrease in the transition temperature and an increase in the upper-shelf energy.

Fig. 7 Correlation of (a) Charpy V-notch impact energy and (b) crystallinity with nil-ductility transition temperature (NDTT) for three steels: A, 60 mm ($2\frac{3}{8}$ in.) thick old carbon-manganese steel (0.21% C) with a yield strength of 355 MPa (51 ksi); B, 70 mm ($2\frac{3}{4}$ in.) thick modern carbon-manganese steel (0.114C-0.29Ni-0.025Nb-0.022 Cu) with a yield strength of 369 MPa (54 ksi); and C, 50 mm (2 in.) thick TMCP steel (0.11C-0.23Ni-0.03Nb-0.24Cu) with a yield strength of 506 MPa (73 ksi). Source: Ref 22

Figure 7 also presents nil-ductility transition temperature (NDTT) results for the three steels as determined by the drop-weight test (ASTM E 208). The results show that the NDTT for each steel corresponds to a different location on the CVN curve. The old steel, A, has an NDTT of -30 °C (-20 °F), which corresponds to a CVN transition temperature at 45 J (33 ft · lbf) and 85% crystallinity. The NDTT of B, the modern normalized steel, is -40 °C (-40 °F), which corresponds to a CVN transition temperature at 235 J (173 ft · lbf) and 8% crystallinity. The NDTT of C, the TMCP steel, is -60 °C (-75 °F), which corresponds to a CVN transition temperature at 200 J (150 ft · lbf) and 15% crystallinity.

Test data obtained for API 2W grade 50, an 89 mm ($3\frac{1}{2}$ in.) thick TMCP steel, indicate a similar relationship between the NDTT and the CVN transition curve (Ref 23). The API 2W grade 50 steel has an NDTT of $-60\text{ }^{\circ}\text{C}$ ($-75\text{ }^{\circ}\text{F}$), which corresponds to CVN impact energy at NDTT of about 200 J (150 ft · lbf); the CVN energy at a CTOD value of 0.25 mm (0.010 in) is about 150 J (110 ft · lbf) (Fig. 8).

Fig. 8 Correlation of (a) CVN impact energy and crack tip opening displacement and (b) crystallinity with nil-ductility transition temperature for API 2W grade 50, a TMCP steel with a thickness of 89 mm ($3\frac{1}{2}$ in.)

These test results show that modern steels have higher fracture toughness and lower NDTT than older steels. However, the results also raise questions about the suitability of the current practice of assessing the transition temperature of modern steels based on a CVN energy level of 25 to 45 J (18 to 33 ft · lbf) as shown in Table 4. For older steels, CVN energy of 45 J (33 ft · lbf) corresponds to a temperature that is about the same as the NDTT, while for modern steels it corresponds to a temperature that is about 40 to 60 $^{\circ}\text{C}$ (105 to 140 $^{\circ}\text{F}$) lower than the NDTT. This difference in steel behavior needs to be addressed in both design codes and steel specifications.

Fracture Toughness of Welded Structures

Assessing the fracture toughness of offshore structural steel involves evaluating not only base plate toughness but also HAZ and weld metal toughness. Although both HAZ toughness and weld metal toughness requirements are usually included in fabrication specifications, HAZ toughness requirements are sometimes specified in the steel purchase agreement. Because the small amount of material at the tip of the sharp fatigue crack can be examined with CTOD testing, a detailed evaluation of the toughness of the different HAZ regions is possible (Ref 24). This positional accuracy allows for the identification of isolated regions in the HAZ with toughness substantially lower than that of the bulk material. These local brittle zones (LBZs) have occurred during testing for crack extension at stress levels far lower than those at which cracks extended in the bulk material.

The presence of LBZs is not a new problem, nor is it limited to modern steels. In most steels, LBZs are associated with the grain-coarsened regions of the heat-affected zone (GCHAZ). Figure 9 identifies the different HAZ regions in a single-bevel multipass weld. Figure 9 also presents a plan view of a polished section illustrating a method for calculating the length and the percent of the grain-coarsened (GC) regions. Evaluation of wide plate tests suggests that fractures are likely to initiate from the GC areas where the grain size is greater than 80 μm (0.0024 in.), or ASTM No. 4 (Ref 22, 25).

Fig. 9 Regions of the heat-affected zone. (a) The HAZ regions in a single-bevel multipass weld. SCHAZ,

(b) Plan view of a polished weld section showing a method for calculating the length and the percent of the GCHAZ. GC, grain-coarsened

There are several reasons for the current interest in LBZs. The need to reduce costs results in optimized structures that have less redundancy and a large number of highly stressed joints. To reduce welding costs, narrow groove preparation is used that may result in an HAZ that is normal to the loading direction. Also, unlike normalized steel in which the HAZ yield strength is higher than that of the base plate, TMCP steel sometimes has an HAZ yield strength that is lower than that of both the weld metal and the base plate (Fig. 10). Softening of the HAZ can also be expected if thermal cutting is used during fabrication. This behavior can limit the application of thermal cutting to TMCP steels.

Fig. 10 Heat-affected zone hardness of conventional (normalized) steel and TMCP steel

Figure 11 shows the effect of weld metal strength on the CVN toughness of the HAZ for a carbon-manganese steel using the same narrow groove welding procedures. The yield strength of the steel is 458 MPa (66 ksi). Similar results were obtained using CTOD tests; the CGHAZ toughness decreases (that is, transition temperature increases) with increasing weld metal strength. Therefore, a highly overmatched weld metal (that is, a high ratio of weld metal yield strength, Y_w to base metal yield strength Y_b) is not desirable. The increase in weld metal strength appears to cause an unfavorable deformation state (constraint) that reduces toughness and enhances brittle crack initiation and propagation of GC-HAZ. These results also suggest that care must be taken when correlating HAZ toughness values based on simulated microstructure with values obtained from actual welded joints. The combination of lower structural redundancy, higher stresses, and the location of lower-strength heat-affected zones normal to the loading directions can result in situations where fatigue cracks can propagate through more GC regions, thus increasing the possibility of brittle fracture. Toughness values supplied by ASTM and API are established by testing under ideal laboratory conditions and may not reflect actual HAZ toughness values experienced in the field. Customers should expect toughness values to be lower than those specified in standards.

Fig. 11 Plot of impact energy versus temperature to show the effect of weld metal matching (ratio of weld metal yield strength, Y_w , to base plate yield strength, Y_b) on CVN transition curves for the heat-affected zone. Source: Ref 26

Grain-coarsened regions will always exist in structural steels, but their size depends on both the steel and the welding process used. Therefore, it is necessary to identify an acceptable size for these regions. One study indicates that as long as the percentage of GC regions sampled by the crack front of CTOD specimens is less than 7%, no low toughness values can be measured (Fig. 12). Similar evaluations have shown that a major deterioration in CTOD values results only when the GC regions sampled by the crack front exceed 10% (Ref 28).

Fig. 12 Crack tip opening displacement versus the percent of grain-coarsened regions for several structural steels. Source: Ref 27

Steel companies are responding to industry concerns about LBZs by working on the development of LBZ-free steels through appropriate microalloying (Ref 29). The development of an LBZ-free low aluminum-boron steel has been reported (Ref 30). The low aluminum-boron medium nitrogen chemistry (0.009% Al, 0.0024% B, 0.0052% N, with no copper or niobium additions) was designed to nucleate the maximum amounts of boron nitride precipitates during the cooling of the initial thermal cycle in the GHAZ. This is intended to promote the austenite-to-ferrite transformation and to prevent the bainite transformation. Figure 13 compares the LBZ-free steel with a conventional TMCP steel. The two steels are of the 415-MPa (60-ksi) yield strength class. The cumulative distribution of the critical heat-affected zone CTOD values of the two steels were compared using 27 mm ($1\frac{1}{16}$ in.) CTOD specimens. These specimens were machined from joints welded using submerged arc welding with a heat input of 5.0 kJ/mm (125 kJ/in.).

Fig. 13 Heat-affected zone toughness of low aluminum-boron LBZ-free TMCP steel and conventional TMCP steel. Heat input using submerged arc welding in 5.0 kJ/mm (125 kJ/in.). Source: Ref 30

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Introduction

FATIGUE is the progressive, localized, and permanent structural change that occurs in a material subjected to repeated or fluctuating strains at nominal stresses that have maximum values less than (and often much less than) the tensile strength of the material. Fatigue may culminate into cracks and cause fracture after a sufficient number of fluctuations. The process of fatigue consists of three stages:

- Initial fatigue damage leading to crack initiation
- Crack propagation to some critical size (a size at which the remaining uncracked cross section of the part becomes too weak to carry the imposed loads)
- Final, sudden fracture of the remaining cross section

Fatigue damage is caused by the simultaneous action of cyclic stress, tensile stress, and plastic strain. If any one of these three is not present, a fatigue crack will not initiate and propagate. The plastic strain resulting from cyclic stress initiates the crack; the tensile stress promotes crack growth (propagation). Careful measurement of strain shows that microscopic plastic strains can be present at low levels of stress where the strain might otherwise appear to be totally elastic. Although compressive stresses will not cause fatigue, compressive loads may result in local tensile stresses.

In the early literature, fatigue fractures were often attributed to crystallization because of their crystalline appearance. Because metals are crystalline solids, the use of the term crystallization in connection with fatigue is incorrect and should be avoided.

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Fatigue Resistance

Variations in mechanical properties, composition, microstructure, and macrostructure, along with their subsequent effects on fatigue life, have been studied extensively to aid in the appropriate selection of steel to meet specific end-use requirements. Studies have shown that the fatigue strength of steels is usually proportional to hardness and tensile strength; this generalization is not true, however, for high tensile strength values where toughness and critical flaw size may govern ultimate load carrying ability. Processing, fabrication, heat treatment, surface treatments, finishing, and service environments significantly influence the ultimate behavior of a metal subjected to cyclic stressing.

Predicting the fatigue life of a metal part is complicated because materials are sensitive to small changes in loading conditions and stress concentrations and to other factors. The resistance of a metal structural member to fatigue is also affected by manufacturing procedures such as cold forming, welding, brazing, and plating and by surface conditions such as surface, roughness and residual stresses. Fatigue tests performed on small specimens are not sufficient for precisely establishing the fatigue life of a part. These tests are useful for rating the relative resistance of a material and the baseline properties of the material to cyclic stressing. The baseline properties must be combined with the load history of the part in a design analysis before a component life prediction can be made.

In addition to material properties and loads, the design analysis must take into consideration the type of applied loading (uniaxial, bending, or torsional), loading pattern (either periodic loading at a constant or variable amplitude or random loading), magnitude of peak stresses, overall size of the part, fabrication method, surface roughness, presence of fretting or corroded surface, operating temperature and environment, and occurrence of service-induced imperfections.

Traditionally, fatigue life has been expressed as the total number of stress cycles required for a fatigue crack to initiate and grow large enough to produce catastrophic failure, that is, separation into two pieces. In this article, fatigue data are expressed in terms of total life. For the small samples that are used in the laboratory to determine fatigue properties, this is generally the case; but, for real components, crack initiation may be as little as a few percent or the majority of the total component life.

Fatigue data can also be expressed in terms of crack growth rate. In the past, it was commonly assumed that total fatigue life consisted mainly of crack initiation (stage I of fatigue crack development) and that the time required for a minute fatigue crack to grow and produce failure was a minor portion of the total life. However, as better methods of crack detection became available, it was discovered that cracks often develop early in the fatigue life of the material (after as little as 10% of total lifetime) and grow continuously until catastrophic failure occurs. This discovery has led to the use of crack growth rate, critical crack size, and fracture mechanics for the prediction of total life in some applications. Hertzberg's text (Ref 1) is a useful primer for the use of fracture mechanics methods.

Prevention of Fatigue Failure

A thorough understanding of the factors that can cause a component to fail is essential before designing a part. Reference 2 provides numerous examples of these factors that cause fracture (including fatigue) and includes high-quality optical and electron micrographs to help explain factors.

The incidence of fatigue failure can be considerably reduced by careful attention to design details and manufacturing processes. As long as the metal is sound and free from major flaws, a change in material composition is not as effective for achieving satisfactory fatigue life as is care taken in design, fabrication, and maintenance during service. The most effective and economical method of improving fatigue performance is improvement in design to:

- Eliminate or reduce stress raisers by streamlining the part
- Avoid sharp surface tears resulting from punching, stamping, shearing, and so on
- Prevent the development of surface discontinuities or decarburizing during processing or heat treatment
- Reduce or eliminate tensile residual stresses caused by manufacturing, heat treating, and welding
- Improve the details of fabrication and fastening procedures

Control of or protection against corrosion, erosion, chemical attack, or service-induced nicks and other gouges is an important part of proper maintenance of fatigue life during active service life. Reference 3 contains numerous papers pertaining to these subjects.

Symbols and Definitions

In most laboratory fatigue testing, the specimen is loaded so that stress is cycled either between a maximum and a minimum tensile stress or between a maximum tensile stress and a specified level of compressive stress. The latter of the two, considered a negative tensile stress, is given an algebraic minus sign and called the minimum stress.

Applied Stresses. The mean stress, S_m , is the algebraic average of the maximum stress and the minimum stress in one cycle:

$$S_m = \frac{(S_{\max} + S_{\min})}{2} \quad (\text{Eq 1})$$

The range of stress, S_r , is the algebraic difference between the maximum stress and the minimum stress in one cycle:

$$S_r = S_{\max} - S_{\min} \quad (\text{Eq 2})$$

The stress amplitude, S_a , is one-half the range of stress:

$$S_a = \frac{S_r}{2} = \frac{(S_{\max} + S_{\min})}{2} \quad (\text{Eq 3})$$

During a fatigue test, the stress cycle is usually maintained constant so that the applied stress conditions can be written $S_m \pm S_a$, where S_m is the static or mean stress and S_a is the alternating stress equal to one-half the stress range. The positive sign is used to denote a tensile stress, and the negative sign denotes a compressive stress. Some of the possible combination of S_m and S_a are shown in Fig. 1. When $S_m = 0$ (Fig. 1a), the maximum tensile stress is equal to the maximum compressive stress; this is called an alternating stress, or a completely reversed stress. When $S_m = S_a$ (Fig. 1b), the minimum stress of the cycle is zero; this is called a pulsating, or repeated, tensile stress. Any other combination is known as an alternating stress, which may be an alternating tensile stress (Fig. 1c), an alternating compressive stress, or a stress that alternates between a tensile and a compressive value (Fig. 1d).

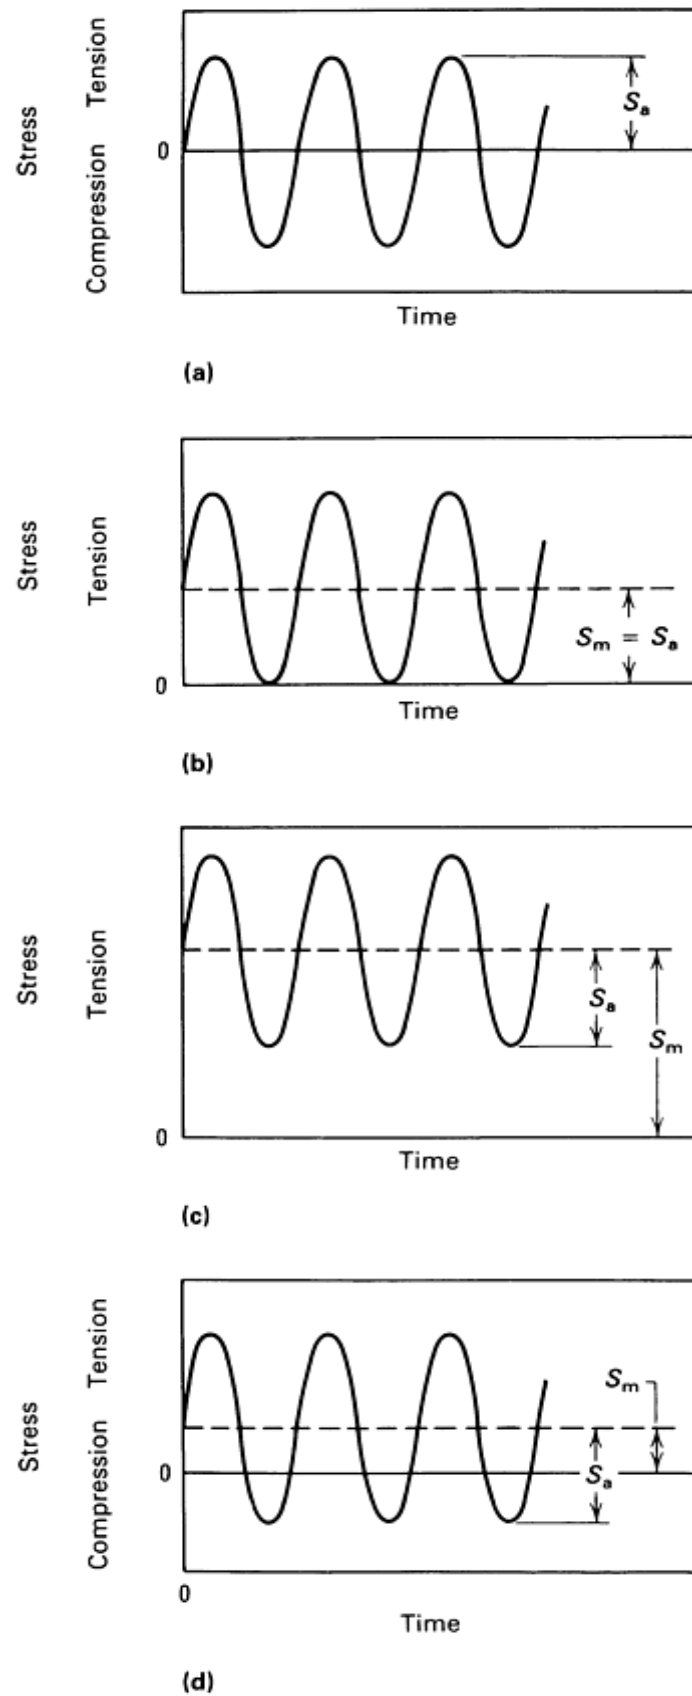

Fig. 1 Types of fatigue test stress. (a) Alternating stress in which $S_m = 0$ and $R = -1$. (b) Pulsating tensile stress in which $S_m = S_a$, the minimum stress is zero, and $R = 0$. (c) Fluctuating tensile stress in which both the minimum and maximum stresses are tensile stresses and $R = \frac{1}{3}$. (d) Fluctuating tensile-to-compressive stress

in which the minimum stress is a compressive stress, the maximum stress is a tensile stress, and $R = -\frac{1}{3}$

Nominal axial stresses can be calculated on the net section of a part (S = force per unit area) without consideration of variations in stress conditions caused by holes, grooves, fillets, and so on. Nominal stresses are frequently used in these calculations, although a closer estimate of actual stresses through the use of a stress concentration factor might be preferred.

Stress ratio is the algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are A , the ratio of the alternating stress amplitude to the mean stress ($A = S_a/S_m$) and R , the ratio of the minimum stress to the maximum stress ($R = S_{\min}/S_{\max}$). The five conditions that R can take range from +1 to -1:

- Stresses are fully reversed: $R = -1$
- Stresses are partially reversed: R is between -1 and zero
- Stress is cycled between a maximum stress and no load: The stress ratio R becomes zero
- Stress is cycled between two tensile stresses: The stress ratio R becomes a positive number less than 1
- An R stress ratio of 1 indicates no variation in stress, and the test becomes a sustained-load creep test rather than a fatigue test

S-N Curves. The results of fatigue tests are usually plotted as the maximum stress or stress amplitude versus the number of cycles, N , to fracture, using a logarithmic scale for the number of cycles. Stress may be plotted on either a linear or a logarithmic scale. The resulting curve of data points is called an S - N curve. A family of S - N curves for a material tested at various stress ratios is shown in Fig. 2. It should be noted that the fully reversed condition, $R = -1$, is the most severe, with the least fatigue life. For carbon and low-alloy steels, S - N curves (plotted as linear stress versus log life) typically have a fairly straight slanting portion with a negative slope at low cycles, which changes with a sharp transition into a straight, horizontal line at higher cycles.

Fig. 2 Best-fit S - N curves for unnotched 300M alloy forging with an ultimate tensile strength of 1930 MPa (280 ksi). Stresses are based on net section. Testing was performed in the transverse direction with a theoretical stress concentration factor, K_t , of 1.0. Source: Ref 4

An S - N curve usually represents the median, or B_{50} , life, which represents the number of cycles when half the specimens fail at a given stress level. The scatter of fatigue lives covers a very wide range and can occur for many reasons other than material variability.

A constant-lifetime diagram (Fig. 3) is a summary graph prepared from a group of S - N curves of a material; each S - N curve is obtained at a different stress ratio. The diagram shows the relationship between the alternating stress amplitude and the mean stress and the relationship between maximum stress and minimum stress of the stress cycle for various constant lifetimes. Although this technique has received considerable use, it is now out of date. Earlier editions of the *Military Standardization Handbook* (Ref 5) used constant lifetime diagrams extensively, but more recent editions (Ref 4) no longer include them.

Fig. 3 Constant-lifetime fatigue diagram for AISI-SAE 4340 alloy steel bars, hardened and tempered to a tensile strength of 1035 MPa (150 ksi) and tested at various temperatures. Solid lines represent data obtained from unnotched specimens; dashed lines represent data from specimens having notches with $K_t = 3.3$. All lines represent lifetimes of ten million cycles. Source: Ref 5

Fatigue limit (or endurance limit) is the value of the stress below which a material can presumably endure an infinite number of stress cycles, that is, the stress at which the S - N diagram becomes and appears to remain horizontal. The existence of a fatigue limit is typical for carbon and low-alloy steels. For many variable-amplitude loading conditions this is true; but for conditions involving periodic overstrains, as is typical for many actual components, large changes in the long-life fatigue resistance can occur (see the discussion in the section "Comparison of Fatigue Testing Techniques" in this article).

Fatigue strength, which should not be confused with fatigue limit, is the stress to which the material can be subjected for a specified number of cycles. The term fatigue strength is used for materials, such as most nonferrous metals, that do not exhibit well-defined fatigue limits. It is also used to describe the fatigue behavior of carbon and low-alloy steels at stresses greater than the fatigue limit.

Stress Concentration Factor. Concentrated stress in a metal is evidenced by surface discontinuities such as notches, holes, and scratches and by changes in microstructure such as inclusions and thermal heat affected zones. The theoretical stress concentration factor, K_t , is the ratio of the greatest elastically calculated stress in the region of the notch (or other stress concentrator) to the corresponding nominal stress. For the determination of K_t , the greatest stress in the region of the notch is calculated from the theory of elasticity or by finite-element analysis. Equivalent values may be derived experimentally. An experimental stress concentration factor is a ratio of stress in a notched specimen to the stress in a smooth (unnotched) specimen.

Fatigue notch factor, K_f , is the ratio of the fatigue strength of a smooth (unnotched) specimen to the fatigue strength of a notched specimen at the same number of cycles. The fatigue notch factor will vary with the life on the $S-N$ curve and with the mean stress. At high stress levels and short cycles, the factor is usually less than at lower stress levels and longer cycles because of a reduction of the notch effect by plastic deformation.

Fatigue notch sensitivity, q , is determined by comparing the fatigue notch factor, K_f , and the theoretical stress concentration factor, K_t , for a specimen of a given size containing a stress concentrator of a given shape and size. A common definition of fatigue notch sensitivity is:

$$q = \frac{K_f - 1}{K_t - 1} \quad (\text{Eq 4})$$

in which q may vary between 0 (where $K_f = 1$, no effect) and 1 (where $K_f = K_t$, full effect). This value may be stated as a percentage. As the fatigue notch factor varies with the position on the $S-N$ curve, so does notch sensitivity. Most metals tend to become more notch sensitive at low stresses and long cycles. If they do not, it may be that the fatigue strengths for the smooth (unnotched) specimens are lower than they could be because of surface imperfections. Most metals are not fully notch sensitive under high stresses and a low number of cycles. Under these conditions, the actual peak stress at the base of the notch is partly in the plastic strain condition. This results in the actual peak stress being lower than the theoretical peak elastic stress used in the calculation of these theoretical stress concentration factor.

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Stress-Based Approach To Fatigue

The design of a machine element that will be subjected to cyclic loading can be approached by adjusting the configuration of the part so that the calculated stresses fall safely below the required line on an $S-N$ plot. In a stress-based analysis, the material is assumed to deform in a nominally elastic manner, and local plastic strains are neglected. To the extent that these approximations are valid, the stress-based approach is useful. These assumptions imply that all the stresses will essentially be elastic.

The $S-N$ plot shown in Fig. 4 presents data for AISI-SAE 4340 steel, heat treated to a tensile strength of 1035 MPa (150 ksi) in the notched and unnotched condition. Figure 5 shows the combinations of cyclic stresses that can be tolerated by the same steel when the specimens are heat treated to different tensile strengths ranging from 860 to 1790 MPa (125 to 260 ksi).

Fig. 4 Room temperature S - N curves for notched and unnotched AISI 4340 alloy steel with a tensile strength of 860 MPa (125 ksi). Stress ratio, R , equals -1.0. Source: Ref 4

Fig. 5 Room temperature S - N curves for AISI 4340 alloy steel with various ultimate tensile strengths and with $R = -1.0$. Source: Ref 4

The effect of elevated temperature on the fatigue behavior of 4340 steel heat treated to 1035 MPa (150 ksi) is shown in Fig. 6. An increase in temperature reduces the fatigue strength of the steel and is most deleterious for those applications in which the stress ratio, R , lies between 0.4 and 1.0 (Fig. 3). A decrease in temperature may increase the fatigue limit of

steel; however, parts with preexisting cracks may also show decreased total life as temperature is lowered, because of accompanying reductions in critical crack size and fracture toughness.

Fig. 6 *S-N* curves at various temperatures for AISI 4340 alloy steel with an ultimate tensile strength of 1090 MPa (158 ksi). Stress ratio, R , equals -1.0. Sources: Ref 4

Figure 7 shows the effect of notches on the fatigue behavior of the ultrahigh-strength 300M steel. A K_t value of 2 is obtained in a specimen having a notch radius of about 1 mm (0.040 in.). For small parts, such a radius is often considered large enough to negate the stress concentration associated with any change in section. The significant effect of notches, even those with low stress concentration factors, on the fatigue behavior of this steel is apparent.

Fig. 7 Room-Temperature *S-N* curves for a 300M steel with an ultimate tensile strength of 2000 MPa (290 ksi) having various notch severities. Stress ratio, *R*, equals 1.0. Source: Ref 4

Data such as those presented in Fig. 3, 4, 5, 6, and 7 may not be directly applicable to the design of structures because these graphs do not take into account the effect of the specific stress concentration associated with reentrant corners, notches, holes, joints, rough surfaces, and other similar conditions present in fabricated parts. The localized high stresses induced in fabricated parts by stress raisers are of much greater importance for cyclic loading than for static loading. Stress raisers reduce the fatigue life significantly below those predicted by the direct comparison of the smooth specimen fatigue strength with the nominal calculated stresses for the parts in question. Fabricated parts in simulated service have been found to fail at less than 50,000 repetitions of load, even though the nominal stress was far below that which could be repeated many millions of times on a smooth, machined specimen.

Correction Factors for Test Data. The available fatigue data normally are for a specific type of loading, specimen size, and surface roughness. For instance, the R.R. Moore rotating-beam fatigue test machine uses a 7.5 mm (0.3 in.) diam specimen that is free of any stress concentrations (because of specimen shape and a surface that has been polished to a mirror finish), and that is subjected to completely reversed bending stresses. For the fatigue limits used in design calculations, Juvinall (Ref 6) suggests the correction of fatigue life data by multiplying the fatigue limit from testing, N_i , by three factors that take into account the variation in the type of loading, part diameter, and surface roughness:

$$\text{Design fatigue limit} = K_l \cdot K_d \cdot K_s \cdot N_i \quad (\text{Eq 5})$$

where K_l is the correction factor for the type of loading, K_d for the part diameter, and K_s for the surface roughness. Values of these factors are given in Table 1 and Fig. 8.

Table 1 Correction factors for surface roughness (K_s), type of loading (K_l), and part diameter (K_d), for fatigue life of steel parts

Factor	Value for loading in		
	Bending	Torsion	Tension
K_1	1.0	0.58	0.9 ^(a)
K_d			
where $d \leq 10$ mm (0.4 in.)	1.0	1.0	1.0
where 10 mm (0.4 in.) $< d \leq 50$ mm (2 in.)	0.9	0.9	1.0
K_s	See Fig. 8.		

Source: Ref 6

(a) A lower value (0.06 to 0.85) may be used to take into account known or suspected undetermined bending because of load eccentricity.

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Strain-Based Approach To Fatigue

A strain-based approach to fatigue, developed for the analysis of low-cycle fatigue data, has proved to be useful for analyzing long-life fatigue data as well. The approach can take into account both elastic and plastic responses to applied loadings. The data are presented on a log-log plot similar in shape to an $S-N$ curve; the value plotted on the abscissa is the number of strain reversals (twice the number of cycles) to failure, and the ordinate is the strain amplitude (half the strain range).

During cyclic loading, the stress-strain relationship can usually be described by a loop, such as that shown in Fig. 9. For purely elastic loading, the loop becomes a straight line whose slope is the elastic modulus, E , of the material. The occurrence of a hysteresis loop is most common. The definitions of the plastic strain range, $\Delta\epsilon_p$, the elastic strain range, $\Delta\epsilon_e$, the total strain range, $\Delta\epsilon$, and the stress range, $\Delta\sigma$, are indicated in Fig. 9. A series of fatigue tests, each having a different total strain range, will generate a series of hysteresis loops. For each set of conditions, a characteristic number of strain reversals is necessary to cause failure.

Fig. 9 Stress-strain hysteresis loop. Source: Ref 7

As shown in Fig. 10, a plot on logarithmic coordinates of the plastic portion of the strain amplitude (half the plastic strain range) versus the fatigue life often yields a straight line, described by the equation:

$$\frac{\Delta e_p}{2} = e'_f (2N_f)^c \quad (\text{Eq 6})$$

where e'_f is the fatigue ductility coefficient, c is the fatigue ductility exponent, and N_f is the number of cycles to failure.

Fig. 10 Ductility versus fatigue life for annealed AISI-SAE 4340 steel. Source: Ref 8

Because the conditions under which elastic strains have the greatest impact on fatigue behavior are the long-life conditions where stress-based analysis of fatigue is appropriate, the effects of elastic strain on fatigue are charted by plotting stress amplitude (half the stress range) versus fatigue life on logarithmic coordinates. As shown in Fig. 11, the result is a straight line having the equation:

$$\frac{\Delta s}{2} = s'_f (2N_f)^b \quad (\text{Eq 7})$$

where s'_f is the fatigue strength coefficient and b is the fatigue strength exponent.

Fig. 11 Strength versus fatigue life for annealed AISI-SAE 4340 steel. The equation for the actual stress amplitude, σ_a , is shown in ksi units. Source: Ref 8

The elastic strain range is obtained by dividing Eq 7 by E :

$$\frac{\Delta e_c}{2} = \frac{S'_f}{E} (2N_f)^b \quad (\text{Eq 8})$$

The total strain range is the sum of the elastic and plastic components, obtained by adding Eq 6 and 8 (see Fig. 12):

$$\frac{\Delta e_c}{2} = e'_f (2N_f)^c + \frac{S'_f}{E} (2N_f)^b \quad (\text{Eq 9})$$

For low-cycle fatigue conditions (frequently fewer than about 1000 cycles to failure), the first term of Eq 9 is much larger than the second; thus, analysis and design under such conditions must use the strain-based approach. For long-life fatigue conditions (frequently more than about 10,000 cycles to failure), the second term dominates, and the fatigue behavior is adequately described by Eq 7. Thus, it becomes possible to use Eq 7 in stress-based analysis and design.

Fig. 12 Total strain versus fatigue life for annealed AISI-SAE 4340 steel. Data are same as in Fig. 10 and 11. Source: Ref 8

Figure 13 shows the fatigue life behavior of two high-strength plate steels for which extensive fatigue data exist. ASTM A 440 has a yield strength of about 345 MPa (50 ksi); the other steel is a proprietary grade hardened and tempered to a yield strength of about 750 MPa (110 ksi). Under long-life fatigue conditions, the higher-strength steel can accommodate higher strain amplitudes for any specified number of cycles; such strains are elastic. Thus, stress and strain are proportional, and it is apparent that the higher-strength steel has a higher fatigue limit. With low-cycle fatigue conditions, however, the more ductile lower-strength steel can accommodate higher strain amplitudes. For low-cycle fatigue conditions (in which the yield strength of the material is exceeded on every cycle), the lower-strength steel can accommodate more strain reversals before failure for a specified strain amplitude. For strain amplitudes of 0.003 to 0.01, the two steels have the same fatigue life, 10^4 to 10^5 cycles. For this particular strain amplitude, most steels have the same fatigue life, regardless of their strength levels. Heat treating a steel to different hardness levels does not appreciably change the fatigue life for this strain amplitude (Fig. 14).

Fig. 13 Total strain versus fatigue life for two high-strength low-alloy (HSLA) steels. Steels are ASTM A 440 having a yield strength of about 345 MPa (50 ksi) and a proprietary quenched and tempered HSLA steel having a yield strength of about 750 MPa (110 ksi). Source: Ref 7

Fig. 14 Effect of hardness level on plot of total strain versus fatigue life. These are predicted plots for typical medium-carbon steel at the indicated hardness levels. The prediction methodology is described under the heading "Notches." in this article.

Fuchs and Stephens's text (Ref 9), *Proceedings of the SAE Fatigue Conference* (Ref 10), and the recently published update to the *SAE Fatigue Design Handbook* (Ref 11) provide much additional detail on the use of state-of-the-art fatigue analysis methods. In fact, the chapter outline for the latter work, shown in Fig. 15, provides an excellent checklist of factors to include in a fatigue analysis.

Define the problem and logical steps to a solution

Evaluate basic materials properties

Choose analytical or experimental approach
(or a combination)

Consider how the fatigue properties
of the real part might differ

Define the forces acting on the structure

Translate loads into stresses and/or
strains and likely sites for crack initiation

Evaluate fatigue life and failure location

Determine whether there is either a
prediction or occurrence of fatigue
failures. If so, consider alternatives

Examine documented case histories for
suggestions of possible course of action

Do failure analysis to help clarify
the source(s) of the problem

Evaluate the need to make changes
in the design and/or analysis

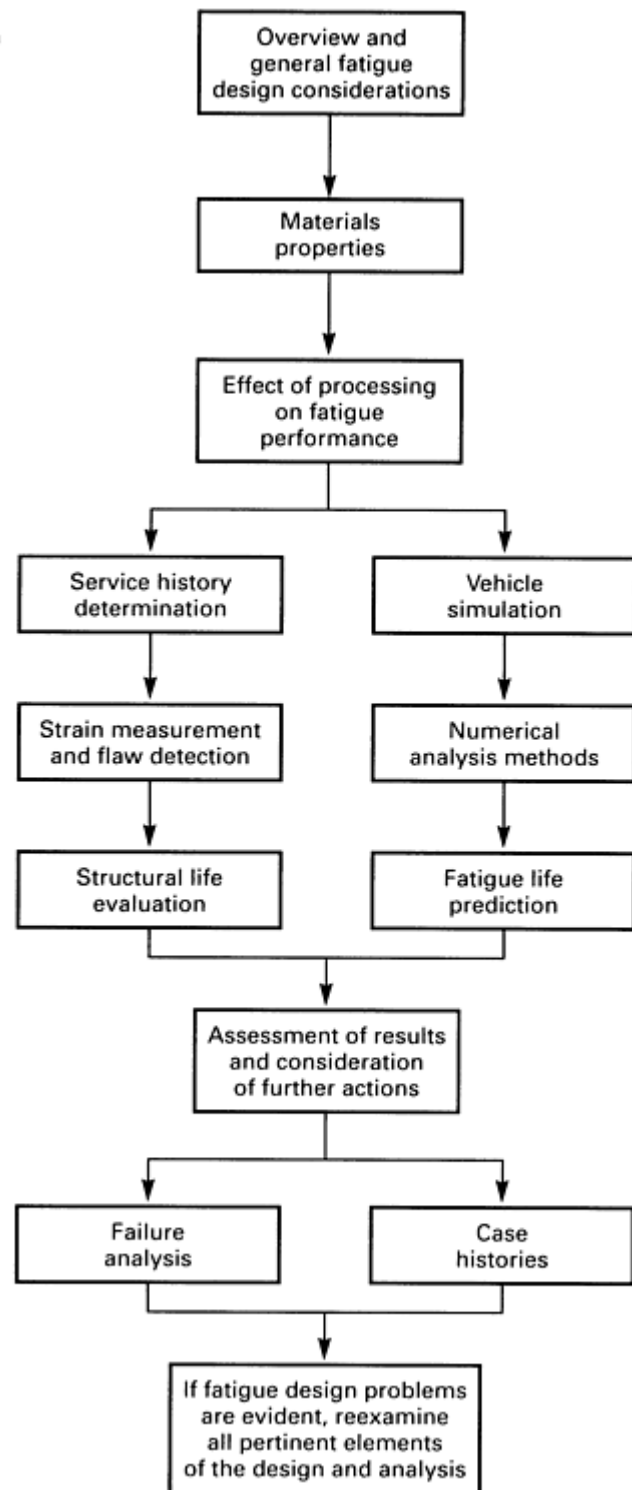

Fig. 15 Checklist of factors in fatigue analysis. Source: Ref 11

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Metallurgical Variables of Fatigue Behavior

The metallurgical variables having the most pronounced effects on the fatigue behavior of carbon and low-alloy steels are strength level, ductility, cleanliness of the steel, residual stresses, surface conditions, and aggressive environments. At least partly because of the characteristic scatter of fatigue testing data, it is difficult to distinguish the direct effects of other variables such as composition on fatigue from their effects on the strength level of steel. Reference 3 addresses some excellent research in the area of microstructure and its effect on fatigue.

Strength Level. For most steels with hardnesses below 400 HB (not including precipitation hardening steels), the fatigue limit is about half the ultimate tensile strength. Thus, any heat treatment or alloying addition that increases the strength (or hardness) of a steel can be expected to increase its fatigue limit as shown in Fig. 5 for a low-alloy steel (AISI 4340) and in Fig. 16 for various other low-alloy steels as a function of hardness. However, as shown in Fig. 14 for medium-carbon steel, a higher hardness (or strength) may not be associated with improved fatigue behavior in a low-cycle regime ($<10^3$ cycles) because ductility may be a more important factor.

Fig. 16 Effect of carbon content and hardness on fatigue limit of through-hardened and tempered 4140, 4053, and 4063 steels. See the sections "Composition" and "Scatter of Data" in this article for additional discussions.

Ductility is generally important to fatigue life only under low-cycle fatigue conditions. Exceptions to this include spectrum loading where there is an occasional overload with millions of smaller cycles, or extremely brittle materials

where crack propagation dominates. The fatigue-ductility coefficient, ϵ'_f , can be estimated from the reduction in area occurring in a tension test.

Cleanliness of a steel refers to its relative freedom from nonmetallic inclusions. These inclusions generally have a deleterious effect on the fatigue behavior of steels, particularly for long-life applications. The type, number, size, and distribution of nonmetallic inclusions may have a greater effect on the fatigue life of carbon and alloy steel than will differences in composition, microstructure, or stress gradients. Nonmetallic inclusions, however, are rarely the prime cause of the fatigue failure of production parts; if the design fatigue properties were determined using specimens containing inclusions representative of those in the parts, any effects of these inclusions would already be incorporated in the test results. Great care must be used when rating the cleanliness of a steel based on metallographic examination to ensure that the limited sample size (volume rated) is representative of the critical area in the final component.

Points on the lower curve in Fig. 17 represent the cycles to failure for a few specimens from one bar selected from a lot consisting of several bars of 4340H steel. Large spherical inclusions, about 0.13 mm (0.005 in.) in diameter, were observed in the fracture surfaces of these specimens. The inclusions were identified as silicate particles. No spherical inclusions larger than 0.02 mm (0.00075 in.) were detected in the other specimens.

Fig. 17 Effect of nonmetallic inclusion size on fatigue. Steels were two lots of AISI-SAE 4340H; one lot (lower curve) contained abnormally large inclusions; the other lot (upper curve) contained small inclusions.

Large nonmetallic inclusions can often be detected by nondestructive inspection; steels can be selected on the basis of such inspection. Vacuum melting, which reduces the number and size of nonmetallic inclusions, increases the fatigue limit of 4340 steel, as can be seen in Table 2. Improvement in fatigue limit is especially evident in the transverse direction.

Table 2 Improvement in the fatigue limits of SAE 4340 steel with the reduction of nonmetallic inclusions by vacuum melting compared to electric furnace melting

	Longitudinal fatigue limit ^(a)		Transverse fatigue limit ^(a)		Ratio of transverse to longitudinal	Hardness, HRC
	MPa	ksi	MPa	ksi		
Electric furnace melted	800	116	545	79	0.68	27

Vacuum melted	960	139	825	120	0.86	29
---------------	-----	-----	-----	-----	------	----

Source: Ref 12

(a) Determined in repeated bending fatigue test ($R = 0$).

Surface conditions of a metal part, particularly surface imperfections and roughness, can reduce the fatigue limit of the part. This effect is most apparent for high-strength steels. The interrelationship between surface roughness, method of producing the surface finish, strength level, and fatigue limit is shown in Fig. 8, in which the ordinate represents the fraction of fatigue limit relative to a polished test specimen that could be anticipated for the combination of strength level and surface finish.

Fretting is a wear phenomenon that occurs between two mating surfaces. It is adhesive in nature, and vibration is its essential causative factor. Usually, fretting is accompanied by oxidation. Fretting usually occurs between two tight-fitting surfaces that are subjected to a cyclic, relative motion of extremely small amplitude. Fretted regions are highly sensitive to fatigue cracking. Under fretting conditions, fatigue cracks are initiated at very low stresses, well below the fatigue limit of nonfretted specimens.

Decarburization is the depletion of carbon from the surface of a steel part. As indicated in Fig. 18, it significantly reduces the fatigue limits of steel. Decarburization of from 0.08 to 0.75 mm (0.003 to 0.030 in.) on AISI-SAE 4340 notched specimens that have been heat treated to a strength level of 1860 MPa (270 ksi) reduces the fatigue limit almost as much as a notch with $K_t = 3$.

Fig. 18 Effect of decarburization on the fatigue behavior of a steel

When subjected to the same heat treatment as the core of the part, the decarburized surface layer is weaker and therefore less resistant to fatigue than the core. Hardening a part with a decarburized surface can also introduce residual tensile stresses, which reduce the fatigue limit of the material. Results of research studies have indicated that fatigue properties lost through decarburization can be at least partially regained by recarburization (carbon restoration in the surfaces).

Residual Stresses. The fatigue properties of a metal are significantly affected by the residual stresses in the metal. Compressive residual stresses at the surface of a part can improve its fatigue life; tensile residual stresses at the surface reduce fatigue life. Beneficial compressive residual stresses may be produced by surface alloying, surface hardening, mechanical (cold) working of the surface, or by a combination of these processes. In addition to introducing compressive residual stresses, each of these processes strengthens the surface layer of the material. Because most real components also receive significant bending and/or torsional loads, where the stress is highest at the surface, compressive surface stresses can provide significant benefit to fatigue.

Surface Alloying. Carburizing, carbonitriding, and nitriding are three processes for surface alloying. The techniques required to achieve these types of surface alloying are discussed in *Heat Treating*, Volume 4 of *ASM Handbook*. In these processes, carbon, nitrogen, or both elements are introduced into the surface layer of the steel part. The solute atoms strengthen the surface layer of the steel and increase its bulk relative to the metal below the surface. The case and core of a carburized steel part respond differently of the same heat treatment; because of its higher carbon content, the case is harder after quenching and harder after tempering. To achieve maximum effectiveness of surface alloying, the surface layer must be much thinner than the thickness of the part to maximize the effect of the residual stresses; however, the surface layer must be thick enough to prevent operating stresses from affecting the material just below the surface layer. Figure 19 shows the improvement in fatigue limit that can be achieved by nitriding. A particular advantage of surface alloying in the resistance to fatigue is that the alloyed layer closely follows the contours of the part.

Fig. 19 Effect of nitriding and shot peening on fatigue behavior. Comparison between fatigue limits of crankshafts (*S-N* bands) and fatigue limits of separate test bars, which are indicated by plotted points at right. Steel was 4340.

Surface Hardening. Induction, flame, laser, and electron beam hardening selectively harden the surface of a steel part; the steel must contain sufficient carbon to permit hardening. In each operation, the surface of the part is rapidly heated, and the part is quenched either by externally applied quenchant or by internal mass effect. This treatment forms a surface

layer of martensite that is bulkier than the steel beneath it. Further information on these processes may be found in *Heat Treating*, Volume 4 of *ASM Handbook*. Induction, flame, laser, and electron beam hardening can produce beneficial surface residual stresses that are compressive; by comparison, surface residual stresses resulting from through hardening are often tensile. Figure 20 compares the fatigue life of through-hardened, carburized, and induction-hardened transmission shafts.

Steel	Surface hardness, HRC	Hardening process
4140	36-42	Through hardened
4320	40-46	Carburized to 1.0-1.3 m (0.040-0.050 in.)
1035	42-48	Induction hardened to 3 mm (0.120 in.) min effective depth (40 HRC)
1137	42-48	Induction hardened to 3 mm (0.120 in.) min effective depth (40 HRC)

Fig. 20 Effect of carburizing and surface hardening on fatigue life. Comparison of carburized, through-hardened, and induction-hardened transmission shafts tested in torsion. Arrow in lower bar on chart indicates that one shaft had not failed after the test was stopped at the number of cycles shown.

Figure 21 shows the importance of the proper case depth on fatigue life; the hardened case must be deep enough to prevent operating stresses from affecting the steel beneath the case. However, it should be thin enough to maximize the effectiveness of the residual stresses. Three advantages of induction, flame, laser, or electron beam hardening in the resistance of fatigue are:

- The core may be heat treated to any appropriate condition
- The processes produce relatively little distortion

- The part may be machined before heat treatment

Fig. 21 Effect of case depth on fatigue life. Fatigue tests on induction-hardened 1038 steel automobile axle shafts 32 mm ($1\frac{1}{4}$ in.) in diameter. Case depth ranges given on the chart are depths to 40 HRC. Shafts with lower fatigue life had a total case depth to 20 HRC of 4.5 to 5.2 mm (0.176 to 0.206 in.), and shafts with higher fatigue life, 6.4 to 7.0 mm (0.253 to 0.274 in.). Load in torsion fatigue was 2030 N · m (1500 ft · lbf), and surface hardness was 58 to 60 HRC after hardening.

Mechanical working of the surface of a steel part effectively increases the resistance to fatigue. Shot peening and skin rolling are two methods for developing compressive residual stresses at the surface of the part. The improvement in fatigue life of a crankshaft that results from shot peening is shown in Fig. 19. Shot peening is useful in recovering the fatigue resistance lost through decarburization of the surface. Decarburized specimens similar to those described in Fig. 18 were shot peened, raising the fatigue limit from 275 MPa (40 ksi) after decarburizing to 655 MPa (95 ksi) after shot peening.

Tensile residual stresses at the surface of a steel part can severely reduce its fatigue limit. Such residual stresses can be produced by through hardening, cold drawing, welding, or abusive grinding. For applications involving cyclic loading, parts containing these residual stresses should be given a stress relief anneal if feasible.

Aggressive environments can substantially reduce the fatigue life of steels. In the absence of the medium causing corrosion, a previously corroded surface can substantially reduce the fatigue life of the steel, as shown in Fig. 8. Additional information on corrosion fatigue is contained in Volumes 8 and 13 of *ASM Handbook* (formerly 9th Edition *Metals Handbook*).

Grain size of steel influences fatigue behavior indirectly through its effect on the strength and fracture toughness of the steel. Fine-grained steels have greater fatigue strength than do coarse-grained steels.

Composition. An increase in carbon content can increase the fatigue limit of steels, particularly when the steels are hardened to 45 HRC or higher (Fig. 16). Other alloying elements may be required to attain the desired hardenability, but they generally have little effect on fatigue behavior.

Microstructure. For specimens having comparable strength levels, resistance to fatigue depends somewhat on microstructure. A tempered martensite structure provides the highest fatigue limit. However, if the structure as-quenched is not fully martensitic, the fatigue limit will be lower (Fig. 22). Pearlitic structures, particularly those with coarse pearlite, have poor resistance to fatigue. *S-N* curves for pearlitic and spheroidized structures in a eutectoid steel are shown in Fig. 23.

Fig. 22 Effect of martensite content on fatigue limit. Data are based on standard rotating-beam fatigue specimens of alloy steels 6.3 mm (0.250 in.) in diameter with polished surfaces.

Property	Spheroidite	Pearlite

Fig. 23 Effect of microstructure on fatigue behavior of carbon steel (0.78% C, 0.27% Mn, 0.22% Si, 0.016% S, and 0.011% P)

Macrostructure differences typical of those seen when comparing ingot cast to continuously cast steels can have an effect on fatigue performance. While there is no inherent difference between these two types of steel after rolling to a similar reduction in area from the cast ingot, bloom, or billet, ingot cast steels will typically receive much larger reductions in area (with subsequent refinement of grain size and inclusions) than will continuously cast billets when rolled to a constant size. Therefore, the billet size of continuously cast steels becomes important to fatigue, at least as it relates to the size of the material from which the part was fabricated.

A significant amount of research has shown that for typical structural applications, strand cast reduction ratios should be above 3:1 or 5:1, although many designers of critical forgings still insist on reduction ratios greater than 10:1 or 15:1. These larger reduction ratio requirements will frequently preclude the use of continuously cast steels because the required caster size would be larger than existing equipment. While this may not be a major problem at this time, steel trends suggest that there will be very little domestic and almost no off-shore ingot cast material available at any cost within the next two decades. The problem will be reduced as larger and larger casters, approaching bloom and ingot sizes, are installed.

Creep-Fatigue Interaction. At temperatures sufficiently elevated to produce creep, creep-fatigue interaction can be a factor affecting fatigue resistance. Information on creep-fatigue interaction is contained in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume.

The orientation of cyclic stress relative to the fiber axis or rolling direction of a steel can affect the fatigue limit of the steel. Figure 24 shows the difference between the fatigue limit of specimens taken parallel to the rolling direction and those taken transverse to it. Any nonmetallic inclusions present will be elongated in the rolling direction and will reduce fatigue life in the transverse direction. The use of vacuum melting to reduce the number and size of nonmetallic inclusions therefore can have a beneficial effect on transverse fatigue resistance (Table 2).

Steel	No. of tests ^(a)	Average tensile strength, MPa (ksi)	Hardness, HRC
Longitudinal tests			
4027	11	1179 (171)	37-39
4063	12	1682 (244)	47-48
4032	11	1627 (236)	46-48
Transverse tests			
4027	10	1130 (164)	34-39.5
4063	9	1682 (244)	47-48.5
4032	10	1254 (182)	47.5-48.5

(a) Number of fatigue specimens. For 4140 steel, 50 longitudinal and 50 transverse specimens were tested: for 4340 steel, 10 longitudinal and 10 transverse specimens were used.

Fig. 24 Effect of specimen orientation on fatigue limit. Orientations are relative to the fiber axis resulting from hot working on the fatigue limit of low-alloy steels. Through-hardened and tempered specimens, 6.3 mm (0.250 in.) in diameter, were taken from production billets. Specimens for each grade were from the same heat of steel, but the tensile and fatigue specimens were heat treated separately, accounting for one discrepancy in hardness readings between the chart and the tabulation above. Fatigue limit is for 100×10^6 cycles.

Fatigue Resistance of Steels

Bruce Boardman, Deere and Company, Technical Center

Application of Fatigue Data

The application of fatigue data in engineering design is complicated by the characteristic scatter of fatigue data; variations in surface conditions of actual parts; variations in manufacturing processes such as bending, forming, and welding; and the uncertainty of environmental and loading conditions in service. In spite of the scatter of fatigue data, it is possible to estimate service life under cyclic loading. It is essential to view such estimates for what they are, that is, estimates of the

mean or average performance, and to recognize that there may be large discrepancies between the estimated and actual service lives.

Scatter of Data. Fatigue testing of test specimens and actual machine components produces a wide scatter of experimental results (see Fig. 25 and Ref 10 for examples). The data in Fig. 25 represent fatigue life simulated-service testing of 25 lots of 12 torsion bars each. In this program, the coefficient of variation, C_N , defined as the ratio of the standard deviation of the mean value, of fatigue life was 0.28. In Table 3, the range of values of the coefficient of variation for fatigue strength is compared with those for other mechanical properties.

Table 3 Coefficients of variation for mechanical properties

Mechanical property	Coefficient of variation, $(C_N)^{(a)}$
Elastic modulus	0.03
Ultimate tensile strength	0.05
Brinell hardness	0.05
Tensile yield strength	0.07
Fracture toughness	0.07
Fatigue strength	0.08 to 1.0

Source: Ref 12

(a) Coefficient of variation, C_N , is the standard deviation divided by the mean value.

Fig. 25 Distribution of fatigue lifetimes from simulated service fatigue tests of front suspension torsion bar springs of 5160H steel. Size of hexagonal bar section was 32 mm (1.25 in.); mean service life, 134,000 cycles; standard deviation, 37,000 cycles; coefficient of variations, 0.28.

For specimens tested near the fatigue limit, the probable range of fatigue life becomes so large that it is pointless to compute a coefficient of variation for fatigue life. Instead, values of C_N are calculated for the fatigue limit. Approximately 1000 fatigue specimens were from a single heat of aircraft quality 4340 steel; all were taken parallel to the fiber axis of the steel. The specimens were heat treated to three different strength levels and polished to a surface roughness of 0 to $0.050\ \mu\text{m}$ (0 to $2\ \mu\text{in.}$). Fatigue limits for these specimens are given in terms of the percent surviving 10 million cycles (Fig. 26). It should be noted that the scatter increases as the strength level is increased; a similar trend is shown in Fig. 16.

Fig. 26 Scatter of fatigue limit data. Based on the survival after 10 million cycles of approximately 1000 specimens, at one heat, of AISI-SAE 4340 steel with tensile strengths of 995, 1320, and 1840 MPa (144, 191, and 267 ksi). Rotating-beam fatigue specimens tested at 10,000 to 11,000 rev/min. Coefficients of variation, C_N , range from 0.17 to 0.20.

Variation from heat to heat with the same steel is greater than variation within a single heat. Figure 27 shows the variations in fatigue limit among five heats of 8740 steel; all specimens were hardened and tempered to 39 HRC. Specimens taken from heat E were given a variety of heat treatments, all of which resulted in a hardness of 39 HRC. The variations in fatigue limit resulting from these heat treatments are also shown in Fig. 27.

- (f) Homogenized at 1150 °C (2100 °F) 24 h and air cooled; normalized at 900 °C (1650 °F) 1 hr and air cooled; austenitized at 825 °C (1520 °F) 1 h and oil quenched; tempered 2 h

Fig. 27 Variations in fatigue limit for different heats and heat treatments

Additional scatter of fatigue data is likely to result from variations in case depth, surface finish, dimensions of the part or specimen, or environmental or residual stresses. Axial load tests for fatigue properties are considered more conservative than rotating bending tests but have the advantage of obtaining information on fatigue properties at various mean stresses.

Estimating Fatigue Parameters. In the strain-based approach to fatigue, five parameters (σ'_f , b , ϵ'_f , c , and E) are used to describe fatigue behavior. These parameters can be determined experimentally; typical values (which should not be considered averages or minimums) obtained for several materials are given in Table 4. In the absence of experimentally determined values, these parameters have been estimated from uniaxial tension test results. The use of these parameters (either experimentally determined or estimated values) to predict fatigue behavior only approximates actual behavior and should never be substituted for full-scale testing of actual parts under service conditions.

(a) QT, quenched and tempered.

As described earlier, the fatigue strength coefficient, σ'_f , is the intercept of the true stress amplitude-fatigue life plot at one reversal. The fatigue strength exponent, b , is the slope (always negative) of this line.

For steels with hardnesses below 500 HB, σ'_f may be approximated by:

$$S'_f = S_u + 345 \quad (\text{Eq 101})$$

where σ'_f and S_u , the ultimate tensile strength, are given in MPa, or by:

$$S'_f = S_u + 50 \quad (\text{Eq 102})$$

where σ'_f and S_u are given in ksi. If the tensile strength is not known, it may be approximated at 3.4 MPa (500 psi) times the Brinell hardness number.

The value of the fatigue strength exponent, b , is usually about -0.085. If the steel has been fully annealed, the value of b may be as high as -0.1. If the steel has been severely cold worked, the value of b may be as low as -0.05.

For a fatigue life of more than a million cycles, the use of these parameters in Eq 7 provides a slightly lower estimate of fatigue limit than the frequently used rule of thumb that the fatigue limit is half the ultimate tensile strength.

The fatigue ductility coefficient, ϵ'_f , is approximated by the true fracture ductility, ϵ_f , which can be calculated from the reduction in area in a tension test by:

$$\epsilon'_f \approx \epsilon_f = \ln \left(\frac{100}{100 - \%RA} \right) \quad (\text{Eq 11})$$

If the reduction in area (% RA) can be estimated from hardness levels, typical values of ϵ'_f can then be approximated by the use of Eq 11. For example:

- With hardness less than 200 HB, RA is approximately 65%, and $\epsilon'_f = 1.0$
- With hardness between 200 and 300 HB, RA is approximately 40%, and $\epsilon'_f = 0.5$
- With hardness greater than 400 HB, RA is approximately 10%, and $\epsilon'_f = 0.1$

The fatigue-ductility coefficient, ϵ'_f , should be estimated from a measured percent of RA rather than obtained by using these approximate values, if possible.

The fatigue-ductility exponent, c , has approximately the same value (-0.6) for most ductile steels. Severe cold working may raise the value of c to -0.7; annealing or tempering at a high temperature may reduce c to about -0.5.

The elastic modulus (Young's modulus), E , is the slope of the elastic portion of the uniaxial stress-strain curve. For most steels, it has a value of about 200 GPa (29×10^6 psi). Further information on estimating these fatigue parameters may be found in Ref 10. As a check on estimating, the results should be compared with the data for a similar material in Table 4.

Estimating Fatigue Life. Designers of machine components to be subjected to cyclic loading would like to be able to predict the fatigue life from basic materials parameters and anticipated loading patterns. However, the scatter of fatigue data is so great that the likelihood of accurate predictions is extremely low. The methods and approximations in this article and in Ref 10, 11, and 13, 14, and 15 can provide some indication of fatigue life. Efforts to estimate fatigue life when service temperatures make creep-fatigue interaction a factor are discussed in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume.

In a specific situation, the assessment of the seriousness of fatigue is aided by a knowledge of the cyclic strains involved in fatigue of various lives. Certain generalizations are useful guidelines for ductile steels:

- If the peak localized strains are completely reversed and the total range of strain is less than S_u/E , fatigue failures are likely to occur in a large number of cycles or not at all

- If the total strain range is greater than 2% (amplitude $\pm 1\%$), fatigue failure will probably occur in less than 1000 cycles
- Part configurations that prevent the use of the ductility of the metal and metals that have limited ductility are highly susceptible to fatigue failures

With respect to long-life fatigue, the relative magnitude of the change in fatigue strength due to processing may be crudely estimated by the relative changes produced in ultimate tensile strength and in hardness. If the ductility change is also measured and if the qualitative effects of various processes on different types of metal are known, more refined estimates of the change in fatigue behavior can be made without resorting to extensive fatigue testing.

Fatigue life may be estimated by inserting a calculated strain amplitude and the appropriate materials parameters from Table 4 into Eq 9 and then solving for the number of cycles to failure, N_f . Where deformation is purely elastic, a calculated stress amplitude and Eq 7 may be used. The calculated fatigue life must be adjusted to compensate for stress concentrations, surface finish, and the presence of aggressive environments, as described in Fig. 8 and Ref 6, 7, 8, 9, 10, 11. Alternatively, the calculated stress may be adjusted by using stress concentration factors such as those in Ref 16 and 17. Any of these calculations includes the assumption that the loading is fully reversed ($R = -1$).

Potter (Ref 18) has described a method for approximating a constant-lifetime fatigue diagram for unnotched specimens. Using this method, a series of points corresponding to different lifetimes are calculated and plotted along a diagonal line for $R = -1$. Each of these points is connected by a straight line to the point on another diagonal ($R = 1.0$) that corresponds to the ultimate tensile strength. The calculated lines correspond well with the experimental lines. Generally, the predicted lines represent lower stresses than the actual data. Estimating fatigue parameters from the Brinell hardness number provides more conservative estimates. These results are only approximations, and the methods may not apply for every material.

While the likelihood of an accurate life prediction is relatively low, the use of these procedures is still valuable. There are very few "new" parts designed; most new parts are similar to a previously successful design, scaled up or down or operating at a slightly increased load. These procedures are very useful in estimating the change in life due to a change in design, load, processing, or material.

Cumulative Fatigue Damage. The data presented in this article, and most other published fatigue data, were obtained from constant-amplitude testing; all the load cycles in the test are identical. In actual service, however, the loading can vary widely during the lifetime of a part. There have been many approaches to evaluating the cumulative effects of variations in loading on the fatigue behavior of steels. References 7, 9, 10, 15, 18, and 19 describe methods of analyzing cumulative damage. A few overload cycles can reduce the fatigue life of steel, even though the mean load amplitude lies below the fatigue limit; this effect is shown in Fig. 28. The counting of each load cycle and the relative damage produced must be done with extreme accuracy and care. One method, rain flow counting (described in Ref 7, 9, 10, 15, 19, and 20), has been shown to be most effective. In this method, the cyclic stress-strain properties are applied such that the hysteresis behavior of the material (Fig. 9) is taken into account on each load excursion. Obviously, when there are millions of individual loads involved, the task becomes quite large. Frequently, a complex load or strain history will be simplified into a short block representing a fraction of the whole, and the damage in that block will be predicted. The block can then be repeated until failure, and component life can be predicted based on the fraction of the whole represented by the block. In any event, predicting fatigue behavior under these circumstances is difficult.

Fig. 28 Effect of overstrain on fatigue behavior. Shown here is the effect of periodic large strain cycles on the fatigue life of AISI-SAE 4340 steel hardened and tempered to a yield strength of 1100 MPa (160 ksi). Source: Ref 7

Notches. Fatigue failures in service nearly always start at the roots of notches. Because notches cannot always be avoided in design (though they should be avoided whenever possible), some allowance for notches must be made in calculating nominal stresses during the design process. A fatigue notch factor, K_f , should be introduced into the fatigue life calculations that use Eq 7:

$$S_a = \frac{\sigma_a}{k_f} = \frac{S_f}{k_f} (2N_f)^b \quad (\text{Eq 12})$$

where σ_a is the amplitude of the true stress.

The appropriate value of K_f depends on the shape of the notch, fatigue strength, ductility of the metal, residual stress, and design life of the part. Its value varies between 1 (no notch effect) and the theoretical stress concentration factor, K_t . References 16 and 17 list many useful stress concentration factors.

First estimates of notched fatigue performance may be based on $K_f = K_t$, especially for moderately notched, heat-treated steel parts that are expected to withstand many cycles. A value of $K_f < K_t$ can be used if a more exact value of K_f is available.

For notched parts, the value of K_f may be estimated from the equation:

$$k_f = 1 + \frac{k_f - 1}{1 + a/r} \quad (\text{Eq 13})$$

where r is the notch root radius; a is the material constant depending on strength and ductility.

For heat-treated steel, the following equation may be used to estimate a :

$$a = 0.025 \left(\frac{2070}{S_u} \right)^{1.8} \quad (\text{Eq 14a})$$

where a is given in millimeters and the ultimate tensile strength, S_u , is given in MPa. For steels, values of a range from 0.064 to 0.25 mm. Values of a may also be estimated by using the equation:

$$a = \left(\frac{300}{S_u} \right)^{1.8} \times 10^{-3} \quad (\text{Eq 14b})$$

where a is given in inches and S_u in ksi.

When the required design life is relatively short, the effect of the notch will be even less than indicated by Eq 13 because of the large amount of inelastic strain at the root of the notch.

At low fatigue lives, a notch must be regarded as a strain concentration as well as a stress concentration. The product of the strain concentration factor, K_ϵ , and the stress concentration factor, K_σ , is equal to the square of the theoretical stress concentration factor:

$$K_\epsilon K_\sigma = (K_t)^2 \quad (\text{Eq 15})$$

At long lives, the behavior is nominally elastic so that K_ϵ equals K_σ , and both K_ϵ and K_σ are equal to K_t . At short lives, where K_σ is nominally 1, the strain concentration factor is equal to $(K_t)^2$. Usually, however, K_t is replaced by an effective value of K_f , as in Eq 12. This relation may be rewritten as:

$$(K_f \times \Delta S)^2 = \sigma_a \epsilon_a E \quad (\text{Eq 16})$$

where ΔS is the nominal calculated stress amplitude remote from the stress raiser, σ_a is the amplitude of the true stress (Eq 12), and ϵ_a is the amplitude of the true strain. The value of ϵ_a calculated can be used directly on a fatigue life diagram, such as Fig. 14, to estimate the fatigue life of an actual part.

Mean stresses may be introduced into the above equations by substituting the quantity $(\sigma_f - \sigma_0)$ for σ_f wherever it appears. Mean stresses affect fatigue behavior by increasing the amount of plastic strain whenever the algebraic sum of the mean and alternating stresses exceeds the yield strength.

Although residual stresses may be considered equivalent to mechanically imposed mean stresses when the cyclic stress is low, their effect on fatigue is less than that indicated by their initial value when the stress or strain is high, because the residual stress is "washed out" by repeated slip. The nominal maximum stress is defined as the algebraic sum of the alternating stress and the mean stress. When the nominal maximum stress is larger than the yield strength, S_y , there is little influence on the residual stress regardless of its original magnitude, and the behavior in fatigue will be similar to that of a stress-free member under fully reversed loading. Most change in residual stress occurs during the first few cycles.

Discontinuities. Many features of a material that are not reflected by the usual bulk mechanical properties may have a large influence on its fatigue resistance. Porosity and inclusions may have little effect on the fatigue behavior of a material, provided that they are less than a certain critical size and are not located in a highly stressed region. The critical size depends on the fracture toughness of the material, shape of the pore or inclusion, and stress intensity at the inclusion or pore. Pores and inclusions larger than this critical size can significantly reduce fatigue life, possibly causing failure during the first load application. Surface discontinuities such as folds, seams, score marks, cracks, and corrosion pits greatly influence fatigue behavior. The detrimental effect of these surface discontinuities on fatigue behavior can be somewhat reduced by surface treatments such as shot peening and surface rolling. Anisotropy of the microstructure can be detrimental to fatigue life, particularly if the tensile component of applied stress is nearly perpendicular to the long dimension of elongated grains or stringers. Because it is impractical to eliminate all discontinuities completely, the quantitative influence of discontinuities must be determined by fatigue tests involving the materials, manufacturing processes, and shapes of the parts in question.

Comparison of fatigue testing techniques can show large differences in the results of a life prediction. Socie (Ref 21) discusses four techniques:

- Load life
- Stress life
- Strain life
- Crack propagation

and the application of each. He makes the point that load life, while most accurate, is generally restricted to real parts and is difficult to apply to new designs. He points out that different load application methods, as in axial versus rotating bending, often make large differences in results (Fig. 29). Socie also cautions the user about sequence effects (Fig. 30). Load history A (Fig. 30b) and load history B (Fig. 30c) have similar-appearing strain histories with totally different stress-strain response and fatigue life (Fig. 30a).

Fig. 29 Fatigue data under axial loading and rotating bending loading for 4340 steel. Source: Ref 21

(a)

Fig. 30 Fatigue data (a) showing sequence effects for notched-specimen and smooth-specimen simulations (2024-T4 aluminum, $K_f = 2.0$). Load histories A and B have a similar cyclic load pattern (dS_2) but have slightly different initial transients (ΔS_1) with either (b) a tensile leading edge (first stress peak at $+\Delta S_1/2$) or (c) a compressive leading edge (first stress peak at $-\Delta S_1/2$). The sequence effect on fatigue life (a) becomes more pronounced as ΔS_2 smaller. Source: Ref 21

Ultimately, the fatigue analyst will be required to include and correlate a number of material, shape, processing, and load factors in order to identify the critical locations within a part and to describe the local stress-strain response at those critical locations. The ability to anticipate pertinent factors will greatly affect the final accuracy of the life prediction.

Load data gathering is one remaining topic that must be included in any discussion of fatigue. Reference 21 discusses three load histories, suspension, transmission, and bracket vibration, that typify loads found in the ground vehicle industry. Additionally, there are vastly different histories unique to other industries, like the so-called ground-air-ground cycle in aeronautics. Without the ability to completely and accurately characterize anticipated and, occasionally, unanticipated customer use and resultant loads, the analyst will not be able to predict accurately the suitability of a new or revised design.

The last several years have seen a major change in the ability to gather customer or simulated customer load data. Testing methods have progressed from bulky, multichannel analogue tape recorders (where it took days or weeks before results were available) through portable frequency-modulated telemetry packages (where analysis could be performed immediately at a remote site) to hand-held packages capable of data acquisition and analysis on board the test vehicle in real time. Microelectronics is further reducing size and improving reliability to the point that data can be gathered from within small, complex, moving, hostile assemblies, such as engines.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Introduction

IRON-BASE ALLOYS are susceptible to a number of embrittlement phenomena. Some of these affect a wide range of compositions, while others are specific to a rather narrow range of compositions. These problems promote brittle service failures that may be catastrophic in nature or may reduce the useful service life of a component. This article reviews these embrittlement problems and presents examples of their influence on mechanical properties. These problems arise from compositional, processing, or service conditions, or combinations of these three conditions.

If the embrittlement occurs during processing at the mill, it may be detected during routine testing depending on the degree of embrittlement and the nature of the testing program. The steelmaker is generally aware of the potential problems that particular grades are susceptible to and will check the various well-known parameters that can promote such problems. This starts with an examination of chemical composition, such as gas contents or impurity elements that are known to cause problems. For example, in the melting of ingots for pressure vessels or rotors where temper embrittlement is a potential problem, the selection of scrap for electric furnace melting is based on the scrap impurity level, and every effort is made to keep residual levels of phosphorus, antimony, tin, and arsenic as low as possible. Subsequent impact testing of coupons from the forgings is used to verify the initial toughness. Such information is compared to specification requirements and historical data base information to maintain quality. Special melting practices, such as vacuum carbon deoxidation, have also been adopted for critical composition control. Furthermore, additional knowledge is obtained by surveillance testing and by postmortems on retired forgings.

However, not all potential problems can be detected, or prevented, at the mill. Some arise from handling or fabrication problems. For example, low-carbon sheet steels that are not aluminum killed are roller leveled at the mill prior to shipment to suppress the yield point and prevent strain-age embrittlement. However, if this steel is not formed within a certain time period, the yield point will return, and discontinuous yielding may occur when the sheet is cold formed, resulting in cosmetically damaging Lüders bands on the product. For this and other fabrication problems, postfabrication inspection and testing programs must be properly planned and executed.

Service and environmental conditions can also cause a number of embrittlement problems. Engineers working with steel components that are susceptible to such operating-induced problems must be aware of the potential problems and must establish regular inspection programs to detect problems before they become critical. An excellent example of such programs is the on-site, *in situ* examination of steam piping in electric power generation plants; these examinations make extensive use of field metallography and replication to assess creep damage and predict remnant life.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Embrittlement of Iron

Before discussing the embrittlement of steels, this article will first examine the embrittlement of iron because the number of such studies are few compared to those for steels. Grain-boundary segregation of elements such as oxygen, sulfur, phosphorus, selenium, and tellurium is known to produce intergranular brittle fractures in iron at low temperatures. Studies of the effects of such impurities in pure iron have been greatly aided by the development of Auger electron spectroscopy (AES).

Intercrystalline fractures in iron at low temperatures occur when the carbon content is low. It has been assumed that the absence of carbon is more important than the presence of embrittling grain-boundary impurities. However, impurities must be present, and the role of carbon appears to be one of a competitor for grain-boundary sites when such impurities are present.

Oxygen. A study of the toughness of iron-oxygen alloys found that intergranular embrittlement and a rise in impact transition temperature in iron were produced by oxygen levels of 30 ppm or more (Ref 1). Figure 1 shows the Charpy V-notch impact transition curves from this study for a series of iron-oxygen alloys with increasing oxygen contents (from 10 to 2700 ppm). However, the sulfur levels of the heats were rather high, from 30 to 54 ppm for the alloys shown in Fig. 1, except for the 0.011% O heat, which had 16 ppm S. Because this work was conducted long before the introduction of AES, the true nature of the embrittling grain-boundary element(s) is open to question.

Fig. 1 Charpy V-notch impact energy curves for iron-oxygen alloys with varying oxygen content. Source: Ref 1

Work on high-purity iron found intergranular brittleness at low test temperatures when specimens were quenched from temperatures where carbon was in solution (Ref 2, 3). It was believed that this brittleness was due to oxygen. Lowering the quench temperature reduced the embrittlement. Titanium additions were not found to be helpful in reducing the intergranular embrittlement.

Reference 4 reviews the study from Ref 3 and reports on similar work performed in France that found that sulfur, not oxygen, was the cause of the embrittlement. Tests were done using electrolytic iron containing 35 ppm S and a purified iron containing less than 1 ppm S; each contained 2000 ppm O and varying carbon contents. The purified iron was found to be much less brittle than the electrolytic iron (Fig. 2). At 10 ppm C, the purified iron was free of intergranular fracture; the electrolytic iron fractured intergranularly below the ductile-to-brittle transition temperature (DBTT).

Fig. 2 Transition temperature, T_t , versus carbon content for two different high-purity irons, each containing 2000 ppm O. Source: Ref 4

Reference 5, on the other hand, shows Auger analysis of intergranular fractures of the pure iron specimen from Ref 2 that contained 60 ppm S. Sulfur was not detected on the intergranular fracture, while carbon, nitrogen, and oxygen were. The authors did state that the oxygen peak could possibly be due to oxygen contamination after fracture in the high vacuum used for Auger work (fracture made inside the evacuated chamber).

It has been demonstrated that large variations in oxygen content have no influence on the brittleness of iron (Ref 6). The Charpy U-notch transition temperatures of electrolytic iron and high-purity iron with varying oxygen and carbon contents were determined, as in Ref 4. Figure 3 shows that the DBTTs for these two irons were constant over a wide range of oxygen contents (1 to 2000 ppm). The DBTT of the electrolytic iron (210 °C, or 410 °F) was consistently much higher than that of the high-purity iron (20 °C, or 70 °F). Also, fractures for the electrolytic iron specimens in the brittle range were fully intergranular, whereas those for the high-purity iron were by cleavage. Carbon and sulfur contents were 30 and 35 ppm, respectively, for the electrolytic iron and 10 and less than 3 ppm, respectively, for the high-purity iron. Manganese contents were 12 ppm for the electrolytic iron and less than 0.5 ppm for the high-purity iron, too little to tie up the sulfur completely in the electrolytic iron. Figure 4 shows the results when carbon and oxygen were both varied. When the carbon level was increased to 30 ppm, there was a large improvement in the DBTT, irrespective of the oxygen level. This study also demonstrated that the addition of elements that form sulfide precipitates improved the DBTT.

Fig. 3 Ductile-to-brittle transition temperatures (from tests using Charpy U-notch specimens) as a function of oxygen content for a decarburized electrolytic iron and a high-purity iron with 10 ppm C. Source: Ref 6

Fig. 4 Ductile-to-brittle transition temperatures of high-purity iron as a function of carbon content and oxygen content. Source: Ref 6

On the other hand, a study using irons with less than 2 ppm S and 0.5 ppm C and Auger analysis demonstrated oxygen grain-boundary enrichment of intergranular fractures broken by impact within the AES chamber (Ref 7). Segregation of elements such as sulfur, phosphorus, and nitrogen was not observed on the fracture, but oxygen was detected. For a specimen with a bulk oxygen content of 430 at. ppm, there were two monolayers of oxygen at the intergranular fracture surface. Carbon was not present at the fracture surface, consistent with the very low bulk carbon content. Another specimen with 235 at. ppm O exhibited about 15% cleavage fracture, along with areas that were predominantly intergranular. The study found that for the material with higher oxygen content, quenching specimens from temperatures

of 1103 and 1123 °C (2017 and 2053 °F), near the solubility limit, gave predominantly intergranular low-temperature fractures. When the temperature was lowered from 973 to 773 °C (1783 to 1423 °F), below the solubility limit, the amount of intergranular fracture decreased. Also, if the specimen was slow cooled from temperatures near the solubility limit, low-temperature fractures were fully by cleavage. Therefore, the study concluded that intergranular brittle fracture of iron was due to the oxygen in solution.

Sulfur. The embrittlement of iron by sulfur has been demonstrated by several authors. Prior to Auger analysis, such results were assumed, but without direct proof. Auger work has, indeed, confirmed that sulfur is a potent embrittler of iron, even at bulk levels as low as 10 ppm. Furthermore, the displacement of sulfur on the grain boundaries when carbon is added has been proved by Auger analysis. Low-temperature impact tests performed on three heats of relatively pure iron obtained intergranular fractures, depending on the heat treatment used (Ref. 8). Sulfur contents ranged from 14 to 100 ppm, carbon contents from less than 10 to 70 ppm, and oxygen contents from 8 to 420 ppm. Auger analysis revealed heavy segregation of sulfur to the grain boundaries. No clear evidence of oxygen on the intergranular fractures was obtained.

Other studies have shown the detrimental influence of small sulfur additions (Ref 9, 10). Figure 5, from these studies, shows the DBTT as a function of bulk sulfur content (≤ 60 ppm) and the beneficial influence of carbon additions (≤ 10 to 30 ppm) for iron containing 2000 ppm O. For less than or equal to 10 ppm C, the transition temperature increased from 0 to over 600 °C (30 to >1110 °F) with increasing sulfur content. However, with 25 or 30 ppm C, the influence of sulfur was small. Also demonstrated was the scavenging influence of a 0.5% Al addition, which suppressed embrittlement (constant DBTT) for the full range of sulfur (≤ 60 ppm) tested.

Fig. 5 Influence of sulfur on the transition temperature of purified iron containing 2000 ppm O, and the influence of carbon content on sulfur embrittlement. Increasing carbon content has the beneficial effect of decreasing sulfur embrittlement. Source: Ref 9, 10

Selenium and tellurium are similar to sulfur and are potential embrittlers of pure iron. One study (Ref 10) showed that they do cause embrittlement, but to a lesser degree than sulfur (Fig. 6). In this work, the carbon content was less than 10 ppm, and 2000 ppm O was present. Although selenium and tellurium had less influence on the DBTT, these two elements reduced the absorbed energy values much more than did sulfur. Therefore, in terms of impact energy, the elements can be placed in order of increasing influence as follows: sulfur, selenium, and tellurium. Others have also reported the embrittlement of Fe-0.04% C by 0.02% Te (Ref 11).

Fig. 6 Influence of sulfur, tellurium, and selenium on the transition temperature of purified iron containing up to 10 ppm carbon and approximately 2000 ppm O. Source: Ref 10

Other Impurity Elements. Phosphorus has also been reported to embrittle pure iron (Ref 12, 13). However, both of these studies used materials with a significant sulfur content, and they were performed prior to the development of Auger analysis. However, radioactive tracer analysis demonstrated the segregation of phosphorus at the grain boundaries of an Fe-0.09% P alloy (Ref 12). Phosphorus was reported to be 50 times as prevalent at the grain boundaries as in the grain interiors. Phosphorus does substantially increase the strength of ferrite. Again, the addition of carbon was shown to reduce the influence of phosphorus on embrittlement.

Researchers have also studied phosphorus segregation in pure iron (Ref 14). Again, the specimens contained a significant amount of sulfur, but mechanical properties were not determined. However, a small amount of manganese was present that should precipitate the sulfur as a sulfide. The carbon content was reduced to below 10 ppm. Specimens were austenitized, water quenched, tempered at 850 °C (1560 °F) for 1 h, and then furnace cooled to the aging temperature. Specimens were fractured within the Auger chamber. Phosphorus was observed on the surface of intergranular fractures, but not on cleavage fractures. Auger analysis showed that the amount of phosphorus on the intergranular fractures increased with bulk phosphorus content. Also, as the aging temperature decreased, the grain-boundary phosphorus content increased, and the fracture became more intergranular. When carbon was added (≤ 80 ppm), the grain-boundary phosphorus concentration decreased. A deep-drawing steel containing 7 ppm C, 310 ppm P, and 0.36% Mn fractured intergranularly in the drawing direction, and phosphorus was detected on the grain boundaries (Ref 14). Similar steels with 14 ppm C, 80 ppm P, and 0.38% Mn did not fracture during deep drawing.

A study of the embrittlement of iron by phosphorus, phosphorus and sulfur, and antimony and sulfur demonstrated that the embrittlement was different from that of temper embrittlement in that it was not reversible (Ref 15). Segregation

occurred at all temperatures in ferrite but was negligible or limited in austenite. Quenching from the austenite region produced specimens that fractured by cleavage. When quenched from the two-phase region, fractures did exhibit phosphorus at the grain boundaries. When an Fe-0.2P alloy was furnace cooled from the austenite region, the fracture surface exhibited a layer of nearly pure phosphorus at the grain boundary with a thickness of 1 to 1.5 nm (10 to 15 Å). The ternary alloys containing sulfur exhibited DBTTs of about 350 °C (660 °F). The study concluded that sulfur, even at much lower concentrations than phosphorus, is a more potent embrittler of iron.

Metalloids such as phosphorus, arsenic, antimony, and tin do not produce embrittlement of pure iron containing minor amounts of carbon in the same manner as sulfur, although they do in alloy steels (Ref 16). It has been demonstrated that such elements produce embrittlement of carbide/ferrite and surrounding ferrite/ferrite interfaces (Ref 17). This appears to be a nonequilibrium segregation problem, however.

The influence of tin on high-purity iron and low-carbon steel has been examined (Ref 18). Detailed chemical analyses of the pure iron specimens used were not given in the study, although it was stated that the base metal had a carbon content of 20 ppm and an oxygen content of 400 ppm. The addition of 0.5% Sn to the pure iron reduced the impact strength in the ductile region to such a degree that the absorbed energy was constant up to 70 °C (160 °F). Specimens water quenched from 650 °C (1200 °F) exhibited impact results similar to those of tin-free pure iron, while slowly cooled specimens were embrittled. The addition of 0.15% C to the Fe-0.5Sn alloy did reduce the embrittling influence of tin, and the alloy had better toughness than the pure iron specimen when water quenched from 650 °C (1200 °F). The addition of 0.15% P to the Fe-0.5Sn-0.15C alloy raised the DBTT about 20 °C (36 °F) and lowered the upper-shelf energy when water quenched from 650 °C (1200 °F). The examination of fractured specimens showed a changed from transgranular cleavage to intergranular fracture as the tin content increased, particularly for the slowly cooled specimens.

This survey of the influence of impurities on the embrittlement of pure iron has demonstrated that the design of experiments and the interpretation of results are difficult. Many of the early studies did not recognize the significance of relatively minor amounts of sulfur in the high-purity irons used. It is clear that Auger analysis is required to determine the embrittling species. When sulfur is present in the absence of sulfide-forming elements, it has a dominating influence on properties and behavior. The addition of carbon above about 10 ppm will reduce or eliminate embrittlement effects.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Embrittlement in Carbon Steels and Alloy Steels

Several forms of embrittlement can occur during thermal treatment or elevated-temperature service of carbon and alloy steels. These forms of embrittlement (and the types of steel that some forms specifically affect) are:

- Blue brittleness (carbon steels)
- Quench-age embrittlement (low-carbon steels)
- Strain-age embrittlement (low-carbon steels)
- Aluminum nitride embrittlement (carbon and alloy steels)
- Graphitization (carbon and alloy steels)

Blue Brittleness

Carbon steels generally exhibit an increase in strength and a reduction of ductility and toughness at temperatures around 300 °C (570 °F). Because such temperatures produce a bluish temper color on the surface of the specimen, this problem has been called blue brittleness (Ref 19, 20, 21, 22). It is generally believed that blue brittleness is an accelerated form of strain-age embrittlement. Deformation in the blue-heat range followed by testing at room temperature produces an increase in strength that is greater than when the deformation is performed at ambient temperature. Blue brittleness can be eliminated if elements that tie up nitrogen are added to the steel, for example, aluminum or titanium.

Quench-Age Embrittlement

If a carbon steel is heated to a temperature slightly below its lower critical temperature and then quenched, it will become harder and stronger but less ductile (Ref 23, 24, 25, 26, 27, 28). This problem has been called quench aging or quench-age embrittlement. The degree of embrittlement is a function of time at the aging temperature. Aging at room temperature requires several weeks to reach maximum embrittlement. Lowering the quenching temperature reduces the degree of embrittlement. Quenching from temperatures below about 560 °C (1040 °F) does not produce quench-age embrittlement. Carbon steels with a carbon content of 0.04 to 0.12% appear to be most susceptible to this problem.

Quench aging is caused by the precipitation of carbide and/or nitride from solid solution. One study has reviewed the quench aging of iron-nitrogen, iron-carbon, and iron-carbon-nitrogen alloys (Ref 25). Figure 7 shows the change in hardness, interparticle spacing, and practice size of precipitates in an Fe-0.02N alloy quenched from 500 °C (930 °F) and

aged at 60 °C (140 °F) up to 500 h. The precipitates grew from about 30 nm (300 Å) in diameter after 2 h to about 80 nm (800 Å) in diameter after 500 h. With aging, the hardness increased rapidly to about 150 HV after 10-h aging at 60 °C (140 °F) and then decreased to about 120 HV with aging to 500 h.

Fig. 7 Influence of aging time at 60 °C (140 °F) after quenching from 500 °C (930 °F) on the hardness, particle size, and interparticle spacing for an Fe-0.02N alloy. Source: Ref 25

Low-Carbon Steels. For low-carbon steels, quench aging is due mainly to carbon because the nitrogen level is usually too low to have a substantial effect. Results for a rimming steel containing 0.03% C (Fig. 8) show the increase in hardness with aging time at 60 °C (140 °F) for specimens quenched from 725 °C (1335 °F). The tensile strength increased rapidly to a maximum value after 10 h at 60 °C (140 °F) and then decreased slowly with further aging. The yield strength also increased rapidly and reached a maximum in about the same time but remained constant with continued aging. The elongation and reduction of area decreased as the strength increased; they reached a minimum after 10 h and then increased somewhat with continued aging.

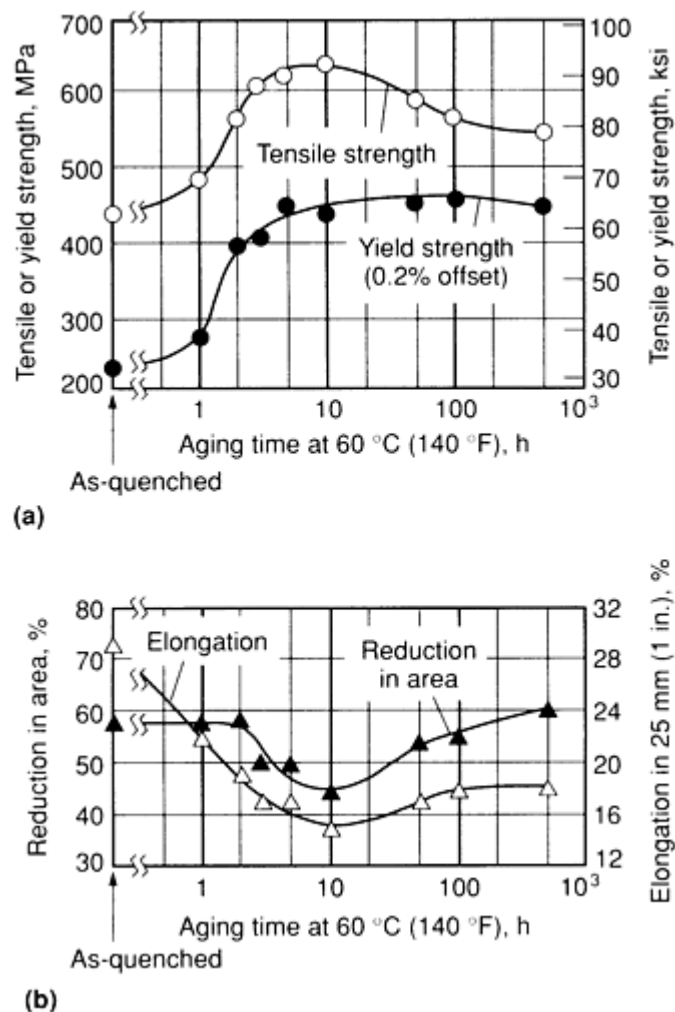

Fig. 8 Influence of aging time at 60 °C (140 °F) after quenching from 725 °C (1335 °F) on the tensile properties of an Fe-0.03C rimming alloy. (a) Tensile and yield strength. (b) Elongation and reduction in area. Source: Ref 25

Iron-Nitrogen and Iron-Carbon Alloys. For iron-nitrogen alloys, two types of nitrides can precipitate during quench aging:

- Face-centered cubic (fcc) Fe_4N platelets form at high temperatures and generally are found at grain boundaries
- Body-centered cubic (bcc) Fe_{16}N_2 nitrides with a circular disk shape precipitate at low temperature on dislocations

This latter type of nitride causes strengthening during quench in iron-nitrogen alloys (Ref 25). Iron-carbon alloys also have two types of carbides that can form during quench aging. Cementite forms at high temperatures, and a low-temperature carbide that is identical in morphology and habit to Fe_{16}N_2 and may be isomorphous with it can also form. With aging, the low-temperature carbide will gradually be replaced by Fe_3C (Ref 25). The phase changes during aging of iron-nitrogen and iron-carbide quench aged steels are discussed in the literature (Ref 28).

Strain-Age Embrittlement

Strain aging occurs in low-carbon steels deformed certain amounts and then aged, which produces an increase in strength and hardness but a loss in ductility (Ref 25, 26, 27, 29, 30, 31, 32, 33, 34). The degree of deformation, or cold work, is

important. Generally, about a 15% reduction in thickness provides the maximum effect. The resulting brittleness varies with the aging temperature and time. Aging at room temperature is very slow, requiring several months to obtain maximum embrittlement. As the aging temperature is increased, the time for maximum embrittlement decreases. Certain coating treatments, such as hot dip galvanizing, can produce a high degree of embrittlement in areas that were cold worked the critical amount; this can lead to brittle fractures. To prevent this problem, the part can be annealed before galvanizing. Alternatively, the use of sheet steels containing elements that tie up nitrogen, for example, aluminum, titanium, zirconium, vanadium, or boron, will prevent strain-age embrittlement.

Strain aging may also lead to stretcher-strain marks (Lüders bands) on cold-formed low-carbon sheet steel components. These marks are cosmetic defects, rather than cracks, but their presence on formed parts is unacceptable (Fig. 9). During tensile loading, sheet steel that is susceptible to this defect will exhibit nonuniform yielding followed by uniform elongation. The elongation at maximum load and the total elongation are reduced, decreasing cold formability. In a nonaluminum-killed sheet steel, a small amount of deformation, typically 1% reduction, will suppress the yield point for several months. This process is referred to as roller levelling or temper rolling (Ref 31). This process is more effective in eliminating the sharp yield point and preventing strain aging than stretching the steel through the Lüders strain, which requires about 4 to 6% reduction. However, if the material is not formed within the safe period, discontinuous yielding will eventually return and impair formability.

Fig. 9 Example of stretcher-strain marks (Lüders bands) on a cold-formed steel part

Results of one study illustrate the influence of strain aging on mechanical properties (Ref 32). Three steels made by different processes were evaluated: Steel A, silicon and aluminum deoxidized steel; Steel B, capped open hearth steel; and Steel C, capped Bessemer steel. Steel C had the highest nitrogen content. Steels B and C had low aluminum contents, while steel A had sufficient aluminum to tie up the nitrogen. Strips of each were normalized and loaded in tension to a permanent strain of 10%. The strips were held at 25, 230, 480, and 650 °C (75, 450, 900, and 1200 °F) for various lengths of time ($\leq 25,000$ h at 25 and 230 °C, or 75 and 450 °F; ≤ 10 h at 480 °C, or 900 °F; and 2 h at 650 °C, or 1200 °F). Hardness, tensile properties, and impact properties (half-width Charpy V-notch specimens) were determined at different aging times.

Figure 10 shows the impact test results for steels A, B, and C strained 10% in tension and aged at room temperature up to 25,000 h. The impact curves are shifted with aging at room temperature for all three steels; steel A exhibits the best aged toughness, and steel C the poorest. Figure 11 shows the increase in hardness for steels A, B, and C aged for times up to

25,000 h at 25 °C (75 °F) and 230 °C (450 °F). Room-temperature aging produced a gradual increase in hardness with time. The maximum hardness was about the same and was reached quickest by steel C and slowest by steel A. The hardness increase with aging at 230 °C (450 °F) was constant for steel A and slowly decreased with aging for steels B and C.

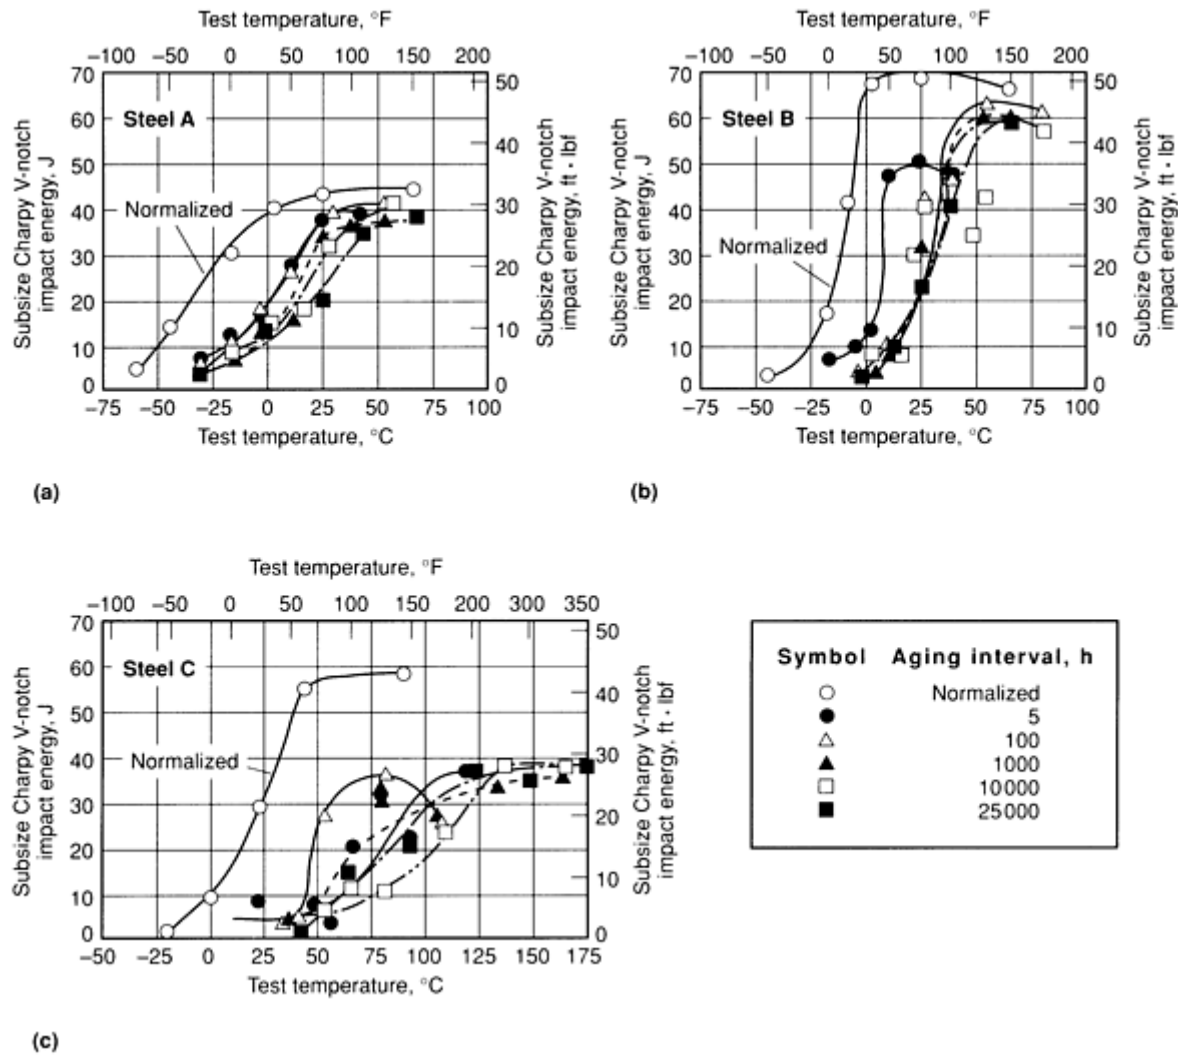

Fig. 10 Influence of straining in tension and aging at 24 °C (75 °F) on the Charpy V-notch (half width) impact strength for three steels. (a) Steel A, silicon and aluminum killed, 0.25% C with 0.013% Al and 0.011% N. (b) Steel B, capped open hearth steel, 0.07% C with 0.005% Al and 0.005% N. (c) Steel C, capped Bessemer steel, 0.08% C with 0.006% Al and 0.016% N. All three steels were strained 10% and aged. Source: Ref 32

Fig. 11 Increase in hardness for steels A, B, and C from Fig. 10 after straining in tension (10%) and aging at 24 and 230 °C (75 and 450 °F) for up to 25,000 h. Source: Ref 32

In low-carbon steels, strain aging is caused chiefly by the presence of interstitial solutes (carbon and nitrogen), although hydrogen is known to produce a lesser effect at low temperatures. These interstitial solutes have high diffusion coefficients in iron and high interaction energies with dislocations. The change in mechanical properties of low-carbon rimming steels with different carbon and nitrogen contents that were prestrained 4% and aged various times at 60 °C (140 °F) has been demonstrated (Fig. 12) (Ref 34). This work clearly demonstrates the detrimental influence of higher carbon and nitrogen contents on strain aging. The solubilities of carbon and nitrogen in iron are quite different. Nitrogen solubility is high in the temperature range where rapid precipitation occurs; the solubility of carbon, in equilibrium with cementite, is very low. Therefore, strain aging that is due to carbon at temperatures below 100 °C (210 °F) is insignificant. However, above 100 °C (210 °F), ϵ carbide can redissolve and produce substantial strain aging (Ref 35). Strain aging attributable to nitrogen is caused by nitrogen that is not tied up with strong nitride formers, for example, aluminum, titanium, zirconium, vanadium, or boron.

Fig. 12 Influence of grain size and aging time at 60 °C (140 °F) on the mechanical property changes caused by strain aging. A 0.038C-0.0042N-0.001Al steel was quenched from 200 °C (390 °F), prestrained 4%, and tested after different aging times. Grain sizes, in grains/mm² (ASTM number), were: specimen 1, 50 (2.7); specimen 2, 195 (4.7); specimen 5, 1850 (7.9). Source: Ref 34

Dynamic Strain Aging. Strain aging can also occur dynamically, that is, aging occurs simultaneously with straining. In this case, the effective strain rate, that is, the dislocation velocity, controls the extent of aging of a particular steel. For normal tensile strain rates, dynamic strain aging occurs in the temperature range of 100 to 300 °C (210 to 570 °F) (which includes temperatures at which blue brittleness occurs). If the interstitial solute content is substantial, dynamic strain aging may be observed at room temperature. At very high strain rates, as in impact testing, dynamic strain aging is observed at temperatures above 400 °C (750 °F), up to about 670 °C (1240 °F). Reference 33 presents dynamic strain aging results for five carbon steels. Carbon and nitrogen are, again, the most important elements in dynamic strain aging. Nitrogen is more important than carbon because of the lower solubility of carbon.

Aluminum Nitride Embrittlement

It is well known that aluminum nitride precipitation in aluminum-killed steels can cause embrittlement and fracture. Several types of problems due to aluminum nitride precipitation have been observed: intergranular fractures in castings (Ref 36, 37, 38, 39, 40, 41, 42, 43), panel cracking in ingots (Ref 44, 45, 46, 47), and reduced hot ductility (Ref 48, 49, 50, 51, 52, 53).

Intergranular fracture in castings, in both the as-cast and heat-treated conditions, have been sporadically observed for many years. The fractures occur at the primary austenite grain boundaries formed during solidification. In as-cast specimens, ferrite films are generally observed at these grain boundaries. The incidence of such cracking has been shown to increase with increases in aluminum and nitrogen contents and with slower cooling rates after casting.

It has been claimed that additions of titanium, zirconium, boron, sulfur, molybdenum, or copper decrease the tendency for cracking (Ref 36). The cooling rate between 1150 and 700 °C (2100 and 1290 °F) is important in controlling the amount of aluminum nitride precipitation. The minimum amount of aluminum nitride required to produce intergranular fracture is lower for alloy steels than for plain carbon steels (0.002 versus 0.004%) (Ref 37). Minimizing the nitrogen content, using the lowest possible amount of aluminum for deoxidation, and increasing the cooling rate after solidification are recommended, and it has been demonstrated that cracking can be prevented by deoxidizing with titanium or zirconium or by combined titanium and aluminum (Ref 37).

Some researchers have claimed that higher levels of phosphorus and sulfur reduce the susceptibility to aluminum nitride intergranular fractures (Ref 38). Nitrogen content has been shown to be more important than aluminum content because aluminum is always present in amounts greater than that required to tie up all of the nitrogen (Ref 41). Higher aluminum contents do, however, increase the solubility temperature of aluminum nitride and provide an additional driving force for precipitation.

Aluminum nitride is known to precipitate with one of two morphologies: plates or dendritic arrays (Ref 38). The dendritic form of aluminum nitride found on the intergranular fracture surfaces of aluminum nitride embrittled castings precipitates from the liquid near the conclusion of solidification (Ref 42). These aluminum nitride dendrites may be nucleation sites for platelike aluminum nitride that precipitates after solidification. The platelike aluminum nitride produces that small, shiny fracture surface facets that are generally observed (Ref 43).

Panel Cracking. Panel cracks are longitudinally oriented surface cracks on the side face of an ingot that generally form near the center of the face and can extend to the midradius of the ingot (Ref 44). Such cracks can occur on more than one ingot face and can run the entire length of the ingot. Panel cracks are observed in aluminum-killed steel ingots, particularly those with 0.4 to 0.7% C (plain carbon steels) or those with somewhat lower carbon contents for alloy steel ingots. These carbon contents lead to ferrite grain-boundary network films with predominantly pearlitic matrix structures. The susceptibility to panel cracking varies with melt practice: electric arc furnace steels are most prone; basic open hearth, basic oxygen furnace, and acid open hearth steels are less prone. Large ingots are more susceptible than small ingots. Stripping of the ingot at as hot a temperature as possible reduces susceptibility. Again, aluminum and nitrogen contents are very important. Panel cracking is not observed with less than 0.015% Al but occurs with increasing frequency with increasing aluminum content above this level. Also, for a given aluminum content, increasing the nitrogen above 0.005% increases panel cracking. Crack surfaces are oxidized but not decarburized. Because the intergranular cracks generally propagate along ferrite/pearlite interfaces, it has been suggested that cracking occurs at relatively low temperatures, probably below 850 °C (1560 °F) (Ref 44).

A statistical study of panel cracking found that the only significant variable was the level of the aluminum addition (Ref 45). It was suggested that cracking began internally and propagated to the surface because of cooling-induced stresses. In a study of panel cracking in two alloy steels, one containing 0.025% Al and 0.008% N and the other having 0.004% Al

and 0.006% N, the former exhibited panel cracking, and the latter did not. Additions of aluminum and titanium to the crack-prone steel composition resulted in the elimination of grain-boundary ferrite networks and freedom from cracking (Ref 46).

A statistical study of panel cracking in low-carbon plate steels found that the steels did not exhibit grain-boundary ferrite networks, but rolled bloom surfaces were heavily cracked in some cases. Some of the observations in this study differ from those of other authors who have studied panel cracking. However, the statistical analysis showed that cracking increased with aluminum content and track time (time between ingot stripping and charging into the soaking pit). Cracking was minimized by holding the aluminum contents to 0.030% or less (Ref 47).

Reduced Hot Ductility. Numerous studies have demonstrated that increasing aluminum and nitrogen contents degrade hot ductility; this influence is most pronounced in the temperature range where aluminum nitride precipitation is greatest (Ref 48, 49, 50, 51, 52, 53). One author found that 3.4% Ni raised the solution temperature of aluminum nitride in En 36 alloy steel by about 100 °C (210 °F) compared to plain carbon steels with the same aluminum and nitrogen levels (Ref 48). Another study evaluated the hot ductility of chromium-molybdenum-vanadium turbine rotor steels with 0.002 to 0.066% Al and 0.007 to 0.014% N. This study showed that nitrogen and residuals (copper, tin, antimony, and arsenic) reduced the hot ductility. The addition of titanium and/or boron improved the hot ductility in the test range (800 to 1000 °C, or 1470 to 1830 °F) where high nitrogen contents were detrimental (Ref 49).

In hot ductility tests on carbon-manganese steels containing 0.032 to 0.073% Al and 0.0073 to 0.0105% N, aluminum nitride was found to reduce deformability and increase the resistance to the deformation of austenite. These trends were enhanced as the aluminum nitride particle size decreased (Ref 50). Other hot ductility tests on low-carbon steels also showed a large decrease in hot ductility because of aluminum nitride precipitation, depending on the volume fraction and size of the precipitates (Ref 51). Five steels were tested containing different levels of soluble aluminum (aluminum not tied up with oxygen) and with nitrogen present as aluminum nitride. Figure 13 shows the reduction in area for hot tensile tests over a range of temperatures for five steels. Steels A and B showed a large decrease in percent reduction in area with increasing temperature; however, steel C did not exhibit such embrittlement. The difference between steels A, B, and C, which all had high levels of nitrogen in the form of aluminum nitride, was the particle size. The smaller aluminum nitride particles in steels A and B were detrimental to hot ductility, while the larger particles in steel C did not cause embrittlement; this agrees with the findings in Ref 50. Steel E contained 0.06% Ti and exhibited the best hot ductility.

(b) No data

Fig. 13 Elevated-temperature tensile test results for five plain carbon steels containing various amounts of aluminum nitride. The nitrogen content (in ppm) of the steels in the form of aluminum nitride was: A, 80; B, 70; C, 72; D, 2; E, 1. Source: Ref 51

An evaluation of the hot ductility of low-carbon killed steels found a substantial reduction in fracture strain between 700 and 800 °C (1290 and 1470 °F). This reduction was most pronounced between 750 and 775 °C (1380 and 1425 °F), where ferrite formed along the prior-austenite grain boundaries. The intergranular fracture surfaces exhibited aluminum nitride and manganese sulfide precipitates (Ref 53).

Hot ductility is also impaired by high residual impurity contents, chiefly those of copper and tin (Ref 54, 55, 56, 57, 58, 59, 60). Examinations of forging and rolling defects have frequently revealed concentrations of elemental copper, high levels of copper and tin, or copper in the scale. Tin residual levels are normally much lower than copper residual levels, but there appears to be a synergistic effect between copper and tin that enhances embrittlement (Ref 54). An examination of longitudinal cracks in medium- and high-carbon steels found that cracking occurred between 700 and 500 °C (1290 and 930 °F) and depended on high copper and tin contents. Aluminum was not added to these steels, but grain-boundary ferrite networks were present. The copper and tin were segregated to the ferrite networks (Ref 55).

Nickel, copper, tin, antimony, and arsenic often become enriched in the subscale layer at the surface of steels heated for forging and rolling in oxidizing atmospheres. It has been shown that tin, antimony, and arsenic residuals alter the solubility of copper in austenite during high-temperature soaking. Because the hot-working temperature is usually above the melting point of elemental copper, liquid copper is produced that will penetrate the austenite grain boundaries and cause cracking by liquid metal embrittlement. Nickel and molybdenum concentrate with copper and raise the melting point of copper; tin, antimony, and arsenic also concentrate at the scale/metal interface and lower the melting point of copper. If copper is not present, tin, antimony, and arsenic have little detrimental effect on hot workability (Ref 56).

It has been shown that tin reduces the solubility of copper in austenite, which is probably more important than its influence on the melting point of copper (Ref 56). Tin reduces the solubility of copper in austenite by a factor of three; therefore, when tin is present, molten copper can form at the surface at lower bulk copper contents. Nickel reduces copper-induced hot shortness, manganese slightly increases hot shortness, arsenic slightly more detrimental than manganese, and tin and antimony are extremely detrimental to copper-induced hot shortness (Ref 58). Chromium decreases the solubility of copper in austenite and increases the susceptibility to copper-induced hot shortness, although its influence is small (Ref 59).

Graphitization

In the early 1940s, several failures of welded joints in high-pressure steam lines occurred because of graphite formation in the region of the weld heat-affected zone that had been heated during welding to the critical temperature of the steel used (Ref 61, 62, 63, 64, 65). Extensive surveys of carbon and carbon-molybdenum steel specimens removed from various types of petroleum refining equipment revealed graphite in about one-third of the 554 specimens examined (Ref 61, 64). In most cases, graphite formation did not occur until about 40,000 h or more at temperatures from 455 to 595 °C (850 to 1100 °F). Aluminum-killed carbon steels were susceptible, but silicon-killed or low-aluminum killed steels were not. The C-0.5Mo steels were more resistant to graphitization than carbon steels, but they were similarly influenced by the nature of the deoxidation practice. Chromium additions and stress relieving at 650 °C (1200 °F) both retarded graphitization.

An examination of the graphitization susceptibility of a number of alloy steels showed that chromium-molybdenum steels used for steam piping, either annealed or normalized, were resistant to graphitization. Nickel and nickel-molybdenum steels did graphite during high-temperature exposure. Chromium-bearing steels did not graphitize and appeared to be quite stable (Ref 65).

The deoxidation practice used in making the steels is the most important parameter influencing graphitization. High levels of aluminum deoxidation strongly promote graphitization for both carbon and carbon-molybdenum steels used for steam lines. While nitrogen appears to retard graphitization, high levels of aluminum remove nitrogen and thus promote graphitization (Ref 66). Molybdenum additions (0.5%) help stabilize cementite but do not fully offset the influence of high aluminum additions. Manganese and silicon both affect graphitization, but their influence is small at the levels used in these alloys. Chromium appears to be the best alloy addition for stabilizing carbides.

Tensile tests of affected steam piping indicate that the graphite present did not affect the tensile strength. Charpy V-notch impact strength, however, was reduced substantially. Localized graphitization near a welded joint appears to be much more damaging to pipe behavior than general, uniform graphitization. The localized graphitization apparently produces notches that concentrate stress and reduce load-bearing capability.

Overheating

The overheating of steels occurs when they are heated to excessively high temperatures prior to hot working (Ref 67, 68, 69, 70, 71, 72, 73, 74, 75, 76). Heating at even higher temperatures will cause incipient grain-boundary melting, a problem known as burning. Thus, overheating occurs in the temperature range between the safe range normally used prior to hot working and the higher range where liquation begins. Hot working after burning generally results in the tearing or rupture of the steel due to the liquid in the grain boundaries. Hot working after overheating generally does not result in cracking; if sufficient hot reduction occurs, the influence of overheating may be minor or negligible. If the degree of hot reduction is small, mechanical properties, chiefly toughness and ductility, will be affected.

Fracture surfaces of overheated steels given limited hot reduction often exhibit a coarse-grain faceted appearance. Such features are most evident after quenching and tempering to develop optimum toughness. Other problems, such as aluminum nitride embrittlement, may also produce a faceted fracture surface. Additional tests are needed to distinguish among these problems (Ref 76).

Although the mechanical properties of burnt steels are always very poor, the mechanical properties of overheated steels show considerable scatter. For tensile tests, the elongation and reduction of area are most affected by overheating and decrease with increasing heating temperature. Fracture faceting and substantial decreases in tensile ductility normally are observed after severe overheating.

Impact properties are usually more sensitive to overheating than is tensile ductility. In examining impact test results, several interrelated features should be examined:

- Change in upper-shelf energy
- Impact strength transition temperature
- Presence of facets

Upper-shelf energy appears to be particularly sensitive to overheating. Figure 14 shows impact energy curves for En 111 alloy steel specimens heated to a variety of temperatures from the normal soaking range to the burning range; no hot working was performed. The specimens were first heated to 950 °C (1740 °F) for 10 min, transferred to the high-temperature zone for 7 min, then transferred back to the furnace at 950 °C (1740 °F) and held for 50 min. They were oil quenched, tempered 1 h at 675 °C (1245 °F), and water quenched to minimize temper embrittlement (more information about temper embrittlement is given in the section "Temper Embrittlement in Alloy Steels" in this article). The use of temperatures up to 1200 °C (2190 °F) produced no change in impact energies, but temperatures above 1200 °C (2190 °F) produced a decrease in upper-shelf energy. The burnt specimens displayed a substantial loss in toughness. Because the pieces were not forged after the burning treatment, they did not fracture.

Fig. 14 Impact energy values versus test temperature for En 111 alloy steel specimens heated to the indicated temperature for 1 h, oil quenched, and tempered for 1 h at 675 °C (1245 °F). Source Ref 68

Presence of Facets. Many of the studies of overheating have been conducted without subsequent hot working after overheating and thus do not simulate actual commercial experience. These studies are of limited value. Numerous theories have been proposed to explain overheating. The examination of facets on fractures of overheated steels reveals that the facet surfaces are covered with fine ductile dimples, and small manganese sulfides can be found within the dimples (because two fracture surfaces are formed, a manganese sulfide particle will be found in either half of the mating dimples after fracture). The facet surfaces correspond to prior-austenite grain surfaces formed during overheating.

As the soaking temperature is raised, manganese sulfide in the steel dissolves (that is, the sulfur goes into solution in the austenite). Dissolved sulfur diffuses toward the austenite grain boundaries, where it reprecipitates. Therefore, overheating changes the size and distribution of sulfides in the steel. The cooling rate through the overheating range also affects the size and dispersion of the intergranular sulfides. In commercial practice, the size of the overheated piece, and any externally applied coolant during hot working, will control this cooling rate.

Steels containing less than 10 ppm S do not overheat, regardless of the heating temperature up to burning. However, this level of sulfur is difficult to obtain. Steels with relatively low sulfur contents, (for example, in the range of 0.001 to 0.005%) are being produced in greater quantities today because of the detrimental influence of sulfur on properties. However, it has been demonstrated that the minimum temperature at which overheating occurs in low-sulfur steels is lower than that for high-sulfur steels (>0.10% S). Overheating problems thus have been experienced in low-sulfur steels heated at temperatures that usually do not cause overheating (Ref 73, 74, 75). Additions of rare earth elements have been shown to prevent overheating by modifying the solubility of the sulfide formed. High-sulfur steels appear to require a greater degree of overheating to cause fracture faceting and impaired properties than do low-sulfur steels.

The problem of overheating is complex. Sulfide dissolution and reprecipitation at the prior-austenite grain boundaries causes fracture faceting and impairment of properties. However, when faceting is observed, mechanical properties may not be significantly affected. Overheating and its influence on properties depend on the sulfur content, the soaking temperature, grain size, the cooling rate through the overheating range, and the degree of hot reduction. Furthermore, the amount of faceting observed on the test fracture depends on the heat treatment (particularly the tempering temperature), the test temperature, the test specimen orientation, and the amount of deformation after sulfide reprecipitation.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Thermal Embrittlement of Maraging Steels

Maraging steels will fracture intergranularly at low impact energies if improperly processed after hot working. This problem, known as thermal embrittlement, occurs when maraging steels that have been heated above 1095 °C (2000 °F) are slowly cooled through, or held within, the temperature range of 980 to 815 °C (1800 to 1500 °F) (Ref 77, 78, 79, 80, 81). The embrittlement is caused by the precipitation of TiC and/or Ti(C,N) on the austenite grain boundaries during cooling through, or holding within, the critical temperature range. The degree of embrittlement increases with time within the critical range. Increased levels of carbon and nitrogen render maraging steels more susceptible to thermal embrittlement. Auger analysis has shown that embrittlement begins with the diffusion of titanium, carbon, and nitrogen to the grain boundaries, and observation of TiC or Ti(C,N) precipitates represents an advanced stage of embrittlement.

Results of a study on thermal embrittlement demonstrate its influence on an 18Ni(250) maraging steel (Ref 77). Plates 12.7 mm (0.5 in.) thick were rolled with finishing temperatures in the range of 1080 to 870 °C (1980 to 1600 °F) and then cooled by three different methods (water, air, and vermiculite). These results showed that the finishing temperature and cooling rate from the finishing temperature had minor effects on the tensile properties but a significant effect on fracture toughness. Figure 15 shows the plane-strain fracture toughness results as a function of finishing temperature (temperature at the end of rolling) and cooling rate for hot-rolled and aged material (Fig. 15a) and for annealed and aged material (Fig.

15b and 15c). In general, vermiculite cooling (slow) and a high finishing temperature produced the lowest toughness, except for specimens water quenched after rolling (Fig. 15b and 15c). Detailed information on maraging steels is available in the article "Maraging Steels" in this Volume.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Quench Cracking

The production of fully martensitic microstructures in steels requires a heat treatment cycle that involves quenching after austenitization. The composition of the steel, its size, and the desired depth of hardening dictate the required quench medium. Certain steels are known to be susceptible to cracking during or slightly after quenching. This is a relatively common problem for tool steels, particularly those that require liquid quenching (Ref 82).

Numerous factors can contribute to cracking susceptibility (Ref 82, 83, 84, 85, 86, 87):

- Carbon content
- Hardenability
- M_s temperature (the temperature at which martensite starts to form)
- Part design
- Surface quality
- Furnace atmosphere
- Heat treatment practice

As the carbon content is raised, the M_s and M_f (temperature at which martensite formation ends) temperatures decrease, and the volumetric expansion and transformation stresses accompanying martensite formation increase. In general, steels with less than 0.35% C are free of quench cracking problems. Such low-carbon steels have higher M_s and M_f temperatures, which allow some stress relief to occur during the quench. Also, transformation stresses are lower, and the lower strength of the martensite formed (low-carbon lath martensite) can accommodate the strains more readily than can a higher-carbon steel.

Alloy steels with ideal critical diameters of 4 or greater are more susceptible to quench cracking than are lower-hardenability steels. Quench crack sensitivity also increases as the severity of the quench rate increases. Control of the austenitizing temperature is also important, particularly for high-carbon tool steels. Excessive retained austenite and coarse-grain structures promote quench cracking. Quench uniformity is important, particularly when liquid quenchants are employed. When high-carbon steels are quenched to form martensite, they are in a highly stressed condition. Therefore, tempering must be done immediately after quenching to relieve these stresses and minimize the risk of cracking. Surface quality is also very important because seams, laps, tool marks, stamp marks, and so on, act as stress concentrators to locate and enhance quench cracking susceptibility (Ref 82).

Quench cracking is a problem that often defies prediction and can be difficult to diagnose. Heat treaters have experienced short time periods in which cracking problems occur frequently and then stop for no apparent reason. Evidence also indicates that quench cracking can be more frequent for certain heats of steel, again for no obvious reason. Instances have

also been documented (Ref 86) in which extensive quench cracking has occurred in material processed from the bottom portion of ingots.

Quench crack fractures are always intergranular. In quenched and tempered steels, proof of quench cracking is often obtained by opening a crack (if necessary) and visually looking for the temper color typical for the temperature used (Ref 88, 89). If the crack occurs during or after quenching but before tempering, and if the crack is open to the furnace atmosphere, a thin oxide layer will form on the surface. The color of the oxide layer depends on its thickness, which in turn depends on the tempering temperature and the steel composition. Quench cracks begin at the surface and propagate inward. They are usually oriented longitudinally or radially unless located by a change in section size, by surface imperfections, or by changes in surface microstructure (such as an interface between hardened and nonhardened areas).

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Temper Embrittlement in Alloy Steels

Temper embrittlement--also known as temper brittleness*, two-step temper embrittlement, or reversible temper embrittlement--is a problem associated with tempered alloy steels that are heated within, or slowly cooled through, a critical temperature range, generally 300 to 600 °C (570 to 1110 °F) for low-alloy steels. This treatment causes a decrease in toughness as determined with Charpy V-notch impact specimens (Ref 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114). It is a particular problem for heavy-section components, such as pressure vessels and turbine rotors, that are slowly cooled through the embrittling range after tempering and also experience service at temperatures within the critical range.

Temper embrittled steels exhibit an increase in their DBTT and a change in fracture mode in the brittle test temperature range from cleavage to intergranular. The DBTT can be assessed in several ways, the most common being the temperature for 50% ductile and 50% brittle fracture (50% fracture appearance transition temperature, or FATT), or the lowest temperature at which the fracture is 100% ductile (100% fibrous criterion). Transition temperatures based on absorbed energy values are not normally employed. Temper embrittlement is reversible; that is, the toughness of embrittled steels can be restored by tempering them above the critical region followed by rapid cooling, for example, water quenching. This decreases the DBTT and changes the low-temperature (that is, below the 50% FATT) intergranular brittle appearance back to the cleavage mode.

Temper embrittlement does not occur in plain carbon steels, only in alloy steels. Also, the degree of embrittlement varies with alloy steel composition. Therefore, the alloying elements present, and their combinations and levels, are important. However, certain impurity elements must be present if temper embrittlement is to occur. The embrittling impurities are, in decreasing order of influence on a weight percent basis, antimony, phosphorus, tin, and arsenic. Of these elements, phosphorus is most commonly present in alloy steels and it has captured the most attention in research studies. Manganese and silicon also increase the susceptibility to embrittlement. Although alloy steels are ferritic in the tempered condition, fracture below the DBTT occurs along prior-austenite grain boundaries where both alloying elements and impurity elements are concentrated.

Effect of Composition on $\Delta FATT$

The proof that antimony, phosphorus, tin and/or arsenic is an essential ingredient(s) for temper embrittlement was obtained in the late 1950s (Ref 90, 91). The change in 50% FATT and 100% fibrous FATT with isothermal aging at 450 °C (230 °F) for up to 1000 h for nickel-chromium and nickel-chromium-molybdenum laboratory heats with controlled compositions and impurity levels was determined. Figures 16 and 17 show some test results for the influence of antimony, phosphorus, tin, and arsenic and aging at 450 °C (840 °F) for 1000 h (Ref 90, 91). Embrittlement was greater for the nickel-chromium steels than for the nickel-chromium-molybdenum steels because of the beneficial influence of molybdenum. The nickel-chromium steels also showed substantially greater embrittlement from the manganese addition than did the nickel-chromium-molybdenum steels. The addition of about 0.7% Si had a smaller and similar embrittling influence for both grades.

Fig. 16 Influence of phosphorus, antimony, arsenic, and tin impurity elements on the temper embrittlement susceptibility of nickel-chromium experimental steels based on the change in (a) 50% FATT and (b) 100%

fibrous FATT after aging at 450 °C (840 °F) for 1000 h. Source: Ref 91

Fig. 17 Influence of phosphorus, antimony, arsenic, and tin impurity elements on the temper embrittlement susceptibility of nickel-chromium-molybdenum experimental steels based on the change in (a) 50% FATT and (b) 100% fibrous FATT after aging at 450 °C (840 °F) for 1000 h. Source: Ref 91

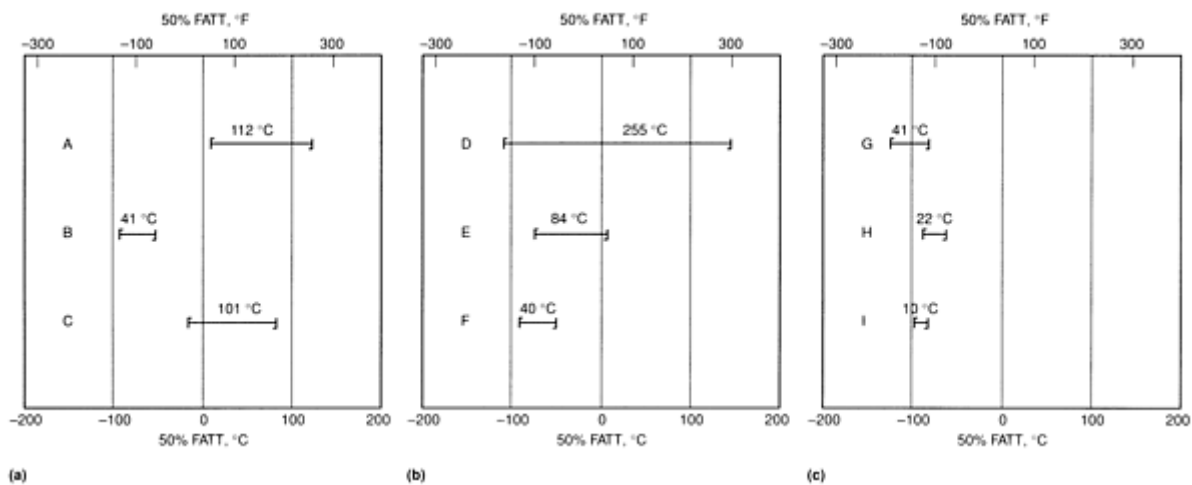

The important role of alloying elements has been clearly demonstrated in tests that also used heats of controlled composition (Ref 92). The tests were performed using 0.4% C alloy steels containing nickel, chromium, or nickel and chromium, as well as a plain carbon steel. Controlled additions of antimony, phosphorus, tin, and arsenic were made to these compositions. The 50% FATT was evaluated for each composition after heat treatment (870 °C, or 1600 °F, for 1 h, oil quench; 625 °C, or 1155 °F, for 1 h, water quench) and after step-cool embrittlement. Figure 18 shows the results for additions of antimony to plain carbon and alloy steels of various analyses. The bars show the 50% FATT after tempering at 625 °C (1155 °F) (left end--not embrittled) and after step cooling (right end--embrittled); the value under the bar is the shift in 50% FATT. The addition of 600 to 800 ppm Sb to the 0.4C-3.5Ni-1.7Cr steel caused a shift in transition temperature of 695 °C (1285 °F). The same steel, but without carbon, exhibited a shift of 222 °C (432 °F), but its hardness was much lower (~80 HRB versus 27 HRC). The steels with only nickel and carbon or chromium and carbon and 600 to 800 ppm Sb exhibited much less embrittlement, while the plain carbon steel was not embrittled by antimony.

Source: Ref 92

Figure 19 shows the results for additions of about 500 ppm each of phosphorus, tin, and antimony to the nickel-chromium-carbon, nickel-carbon, and chromium-carbon steels. The nonembrittled toughnesses of the nickel-chromium-carbon-phosphorus and chromium-carbon-phosphorus alloys were poorer than those of the other alloys shown, probably because of the segregation of phosphorus in austenite. Phosphorus also embrittled the chromium-carbon-phosphorus alloy much more than the nickel-carbon-phosphorus alloy. This is due to an interaction between chromium and phosphorus. Tin appears to embrittle the nickel-chromium-carbon alloy more than phosphorus in that the change in fracture appearance transition temperature (Δ FATT) was greater. However, the grain size of the nickel-chromium-carbon-phosphorus alloy was ASTM No. 8, while that of the nickel-chromium-carbon-tin alloy was ASTM No. 6. Also, the nonembrittled toughness of the alloy containing phosphorus was much poorer. The 50% FATT values for these two compositions are nearly identical and would be even closer if the grain sizes were the same. Otherwise, it appears that tin embrittled the nickel-carbon alloy more than phosphorus, while phosphorus embrittled the chromium-carbon alloy more than tin. Arsenic was a much weaker embrittler. The results in Fig. 18 and 19 clearly show that the combination of nickel and chromium resulted in much greater embrittlement, particularly for additions of antimony and tin. The results for phosphorus show that a strong interaction exists between chromium and phosphorus, while phosphorus causes little embrittlement in nickel steels not containing chromium.

The beneficial influence of molybdenum on phosphorus-induced temper embrittlement has been known for many years (Ref 93, 94). It has also been known that carbon steels are immune to temper embrittlement, but that substantial additions of manganese cause susceptibility to this problem. In addition, high levels of manganese in alloy steels have been known to render them more susceptible to temper embrittlement.

Reference 95 includes an evaluation of the addition of 0.6% Mo, along with controlled antimony, phosphorus, tin, arsenic, and other elements, to AISI 3340 (3.5Ni-1.7Cr-0.4C). The addition of molybdenum eliminated or greatly reduced embrittlement due to step cooling for additions of antimony, tin, and arsenic, but not for additions of phosphorus. The addition of 0.7% Mn to this steel produced substantial embrittlement, which was largely eliminated when 0.6% Mo was added. In this work, it was shown that phosphorus segregates to the austenite grain boundaries during austenitization; antimony does not do this. This work also clearly showed that manganese is an embrittling element, not merely an enhancer of embrittlement.

Later work was conducted to clarify these results (Ref 96). The earlier work had employed specimens with a very coarse grain size (Ref 95). Results with somewhat finer grain sizes, although still rather coarse, showed that 0.5 to 0.6% Mo additions would prevent temper embrittlement caused by phosphorus in 3.5Ni-1.7Cr-0.2C steels for aging times up to 1000 h at 475 and 500 °C (885 and 930 °F). The influence of molybdenum on the prevention of temper embrittlement appears to depend on how much of it is dissolved in the matrix as opposed to how much is tied up in carbides. As more molybdenum becomes tied up in the carbides, the beneficial influence of molybdenum decreases. Therefore, depending on the temperatures experienced and the presence of other strong carbide formers, molybdenum may or may not be able to suppress temper embrittlement.

A major advancement in understanding temper embrittlement was brought about by the development of Auger electron spectroscopy and its application to embrittlement studies in 1969 (Ref 97, 98, 99). This work permitted the direct chemical analysis of segregants on the intergranular fracture surfaces of embrittled specimens. Such work has shown that the embrittling impurity elements are segregated to within the first few monolayers of the embrittled grain boundaries. The degree of enrichment of these elements may be 100 to 10^3 times the bulk concentration. Alloy element segregation at these boundaries was also detected. However, the concentration of these alloying elements was found to be only 2 to 3 times that of the bulk concentration, and the concentration profile from the grain boundary into the grain interior was much shallower than for the impurity elements. Figure 20 shows an example of Auger analysis of antimony, sulfur, and phosphorus segregated to either fracture or free surfaces (Ref 99, 100). These results were obtained by alternate argon ion sputtering (depth profiling) and analysis.

Fig. 20 Normalized intensities of Auger peaks (as a function of depth below the surface) from antimony, sulfur, and phosphorus segregated to grain boundaries or free surfaces (depth profiling by argon ion sputtering). Source: Ref 99

The degree of embrittlement also depends upon the time at temperature within the critical region. Extensive isothermal embrittlement studies were performed on a heat of AISI/SAE 3140 alloy steel (0.39C-0.79Mn-0.30Si-0.028S-0.015P-1.26Ni-0.77Cr-0.02Mo, ASTM No. 8 grain size) (Ref 101). Specimens were austenitized at 900 °C (1650 °F) for 1 h, water quenched, and tempered at 675 °C (1245 °F) for 1 h, and water quenched. This resulted in a hardness of 23 HRC and a transition temperature (100% fibrous criterion) of -83 °C (-117 °F). Specimens were aged at temperatures from 325 to 650 °C (615 to 1200 °F) for times ranging from 4 min to 240 h. Figure 21 shows the time-temperature-embrittlement diagram developed from this work.

Fig. 21 Time-temperature diagram for isothermally temper-embrittled AISI/SAE 3140 alloy steel showing constant embrittlement levels (100% fibrous FATT) for quenched and tempered (675 °C, or 1245 °F, for 1 h), specimens. Source: Ref 101

Because of some minor differences in hardness and apparent inconsistencies in the results for aging at 525 °C (975 °F), additional work was performed (Ref 102). Minor corrections were made in the transition temperatures to account for hardness differences (Fig. 22). Only limited tests were done at temperatures above 575 °C (1065 °F), but the work performed indicated that temper embrittlement occurred at tempering temperatures up to 675 °C (1245 °F), which is close to the lower critical temperature. The diagrams exhibit the classic C-curve appearance. The nose of the curve is at 550 °C (1020 °F), but maximum embrittlement ($\Delta\text{FATT} \approx 100$ °C, or 210 °F) was obtained at 475 to 500 °C (885 to 930 °F) after 240 h aging (the longest time used). Tests done using step cooling showed that the degree of embrittlement that occurred was greater than would have been predicted from the isothermal data.

Fig. 22 Revised time-temperature diagram for temper-embrittled AISI/SAE 3140 alloy steel. Source: Ref 102

The above data was analyzed to predict the degree of grain-boundary phosphorus segregation in this steel (analysis for antimony, tin, and arsenic was not performed, but the amount of these elements was assumed to be very low) (Ref 103). Auger analysis of similar steels was used to calculate the monolayers of phosphorus segregated to the prior-austenite grain boundaries (Fig. 23).

Fig. 23 Time-temperature diagram for the segregation of phosphorus in temper-embrittled AISI/SAE 3140 alloy steel. The numbers next to the curves describe the degree of phosphorus segregated during the embrittlement treatment (not including the 0.06 monolayers of phosphorus segregated prior to the isothermal aging treatments). Source: Ref 103

Microstructure and Grain Size. It is well known that microstructure influences the susceptibility to temper embrittlement and the resulting degree of embrittlement. Because the impurity and alloying elements segregate to the

prior-austenite grain boundaries, grain size has an influence. As the grain size becomes larger, the grain-boundary surface area decreases. Therefore, for a fixed level of impurities and constant embrittling temperatures and time, there will be greater coverage of the grain boundaries in a coarse-grain steel than in a fine-grain steel. However, the distance over which the impurities must diffuse increases as the grain size becomes larger. Nevertheless, coarse-grain steels are recognized to be more severely embrittled than fine-grain steels. Figure 24 shows the results of aging a 0.33C - 0.59Mn - 0.03P - 0.031S - 0.27Si - 2.92Ni - 0.87Cr steel for various times at 500 °C (930 °F) followed by water quenching. Prior to aging, the specimens had been austenitized (at 850 °C, or 1560 °F, for fine-grain specimens; at 1200 °C, or 2190 °F, for coarse-grain specimens) and tempered at 650 °C (1200 °F) for 1 h; they were oil quenched after tempering. The coarse-grain specimens were embrittled to a greater extent than the fine-grain specimens. Similar results have been obtained by others (for example, Ref 105).

Fig. 24 Influence of prior-austenite grain size on the temper embrittlement of a nickel-chromium alloy steel that was heat treated to produce two levels of grain size. The alloy was tempered at 650 °C (1200 °F) and aged various times at 500 °C (930 °F). (a) Actual 100% fibrous FATT. (b) Change in 100% fibrous FATT. Source: Ref 104

Matrix microstructures are also important because they control toughness, for both nonembrittled and embrittled steels. Most studies have evaluated temper embrittlement of martensitic specimens, but a few have compared results for a variety of microstructures as a function of hardness. In general, tempered martensite is more susceptible than tempered bainite to temper embrittlement, but tempered bainite is more susceptible than pearlitic-ferritic structures. This analysis is somewhat misleading, however, because nonembrittled tempered martensite is much tougher than nonembrittled bainite at the same hardness, and after embrittlement, tempered martensite is still tougher than tempered bainite. The same holds true when comparing bainitic and pearlitic-ferritic microstructures. This has been demonstrated for chromium-molybdenum-vanadium steels, as shown in Fig. 25 (Ref 106). The alloy composition was 0.3C-0.91Mn-0.27Si-0.15Ni-1.3Cr-1.2Mo-0.31V-0.025P-0.0045S-0.005 As-0.0008Sb-0.027Sn. The toughness of embrittled tempered martensite was better than that of nonembrittled tempered bainite over the hardness range evaluated. Also, the shift in 50% FATT for tempered martensite increase with hardness and was greater than that for tempered bainite. Only one hardness level was obtained for the ferrite-pearlite condition, and the shift in 50% FATT because of embrittlement (step cooling) was only 5 °C (9 °F).

Embrittlement Predictive Equations. Much of the research on temper embrittlement has concentrated on the influence of composition on susceptibility to temper embrittlement for fixed embrittlement conditions. In general, these studies have concentrated on two basic steel grades, nickel-chromium-molybdenum-vanadium and $2\frac{1}{4}$ Cr-1Mo, which are used for rotors and pressure vessels, respectively.

In a report on an ASTM study of vacuum carbon deoxidized nickel-chromium-molybdenum-vanadium rotor steels isothermally embrittled at 400 °C (750 °F) for 10,000 h (Ref 107), the shift in FATT (Δ FATT) in degrees centigrade was correlated to the impurity content and molybdenum concentration (all in weight percent) by:

$$\Delta\text{FATT} = 7524\text{P} + 7194\text{Sn} + 1166\text{As} - 52\text{Mo} - 450,000(\text{P} \times \text{Sn}) \quad (\text{Eq 1})$$

No significant influence was found for antimony. Equation 1 states that phosphorus, tin, and arsenic increased embrittlement, while molybdenum decreased it. Also, a phosphorus-tin interaction that decreased embrittlement was observed.

A correlation between the 50% FATT and impurity content (*J* factor) for both nickel-chromium-molybdenum-vanadium and $2\frac{1}{4}$ Cr-1Mo steels has been demonstrated (Ref 108). The *J* factor equation is:

$$J = (\text{Mn} + \text{Si})(\text{P} + \text{Sn}) \times 10^4 \quad (\text{Eq 2})$$

where all concentrations are in weight percent.

A more detailed correlation has been provided for nickel-chromium steels doped with manganese, phosphorus, and tin (Ref 109). The equation combines the grain-boundary phosphorus and tin concentrations, the prior-austenite grain size, and the hardness level. Equation 3 was extended to a nickel-chromium-molybdenum-vanadium steel with hardnesses of 20 and 30 HRC, ASTM grain sizes of No. 3 and No. 7, and isothermal embrittlement at 480 °C (895 °F) for 6000 h (Ref 110). The resulting equation was:

$$\begin{aligned} \Delta\text{FATT} = & 4.8\text{P} + 24.5\text{Sn} + 13.75(7 - \text{GS}) \\ & + 2(\text{HRC} - 20) + 0.33(\text{HRC} - 20) \\ & (\text{P} + \text{Sn}) + 0.036(7 - \text{GS})(\text{HRC} - 20) \\ & (\text{P} + \text{Sn}) \end{aligned} \quad (\text{Eq 3})$$

where Δ FATT is in degrees centigrade, the concentrations of phosphorus and tin are the Auger peak-height ratios with respect to iron, HRC is the Rockwell hardness, and GS is the grain size number.

The above discussion shows that carbon steels are immune to temper embrittlement and that only alloy steels are susceptible to it. Both bulk composition and impurity levels are important, although without the latter, temper embrittlement will not occur. The most potent impurity elements are antimony, phosphorus, tin, and arsenic (in order of decreasing potency). Manganese and silicon also promote embrittlement. Alloys containing nickel and chromium in combination are more susceptible than those that contain nickel or chromium separately. Molybdenum additions are effective in retarding or eliminating temper embrittlement when impurities are present. However, to be effective, the molybdenum must be dissolved in the ferritic matrix, not tied up as carbides. Embrittlement occurs because of tempering or service time within a temperature range of 300 to 600 °C (570 to 1110 °F) or because of slow cooling through this range. Coarse-grain material is more susceptible than fine-grain material. The degree of embrittlement is greater for martensite than bainite and least for ferrite-pearlite. However, embrittled martensite is still tougher than nonembrittled bainite, while embrittled bainite is tougher than nonembrittled ferrite-pearlite. Additional information may be found in Ref 110, 111, 112, 113, 114.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Tempered Martensite Embrittlement

Tempered martensite embrittlement (also known as 350 °C or 500 °F, embrittlement and as one-step temper embrittlement) of high-strength alloy steels occurs upon tempering in the range of 205 to 370 °C (400 to 700 °F) (Ref 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132). It differs from temper embrittlement in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In tempered martensite embrittlement, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature. Therefore, temper embrittlement is often called two-step temper embrittlement, while tempered martensite embrittlement is often called one-step temper embrittlement.

Because alloy steels are heat treated to form martensite and then may be tempered within the embrittlement region, this problem has been widely referred to as tempered martensite embrittlement (TME). While some have claimed that structures other than martensite are not embrittled by tempering in this region, it is well established that lower bainite is embrittled when tempered in this region. Other structures, such as upper bainite and pearlite/ferrite, are not embrittled by tempering in this region.

While temper embrittlement is evaluated by the change in the ductile-to-brittle transition temperature, most studies of tempered martensite embrittlement have evaluated only the change in room-temperature impact energy. In general, when an as-quenched alloy steel is tempered, the toughness at room temperature increases with tempering temperature up to about 200 °C (390 °F). However, with further increases in tempering temperature, the toughness decreases. Then, with increasing tempering temperatures above about 400 °C (750 °F), the toughness increases again. This change in toughness with tempering temperature is not apparent when examining hardness or tensile strength data, which generally decrease with increasing tempering temperatures.

To illustrate the influence of tempering temperature on properties, Fig. 26 shows tension, hardness, and Charpy V-notch room-temperature tests for AISI 4340 alloy steel (Ref 115). Room-temperature impact energy decreases with tempering in the critical region (205 to 370 °C, or 400 to 700 °F). The tensile and hardness results show no influence at room temperature. Figure 27 shows room-temperature Charpy V-notch impact energy for AISI 4340 at two different phosphorus levels, 0.003 and 0.03%, as a function of tempering temperature (Ref 128). The low-phosphorus specimens have consistently higher impact energies at all tempering temperatures, and both suffer a reduction in impact energy with tempering in the critical region. As a final example, Fig. 28 shows plane-strain fracture toughness and Charpy V-notch impact energy at room temperature for 300M alloy steel (a high-silicon modification of AISI 4340) as a function of tempering temperature (Ref 127). Both test procedures show somewhat similar results, although the tempering temperature ranges for embrittlement are slightly different.

quenched, and tempered for 1 h. Source: Ref 127

Activating Mechanism. The mechanism causing TME is not as well defined as that which causes temper embrittlement. While many studies have shown that fractures are partly or substantially intergranular, particularly with tempering at about 350 °C (660 °F), other studies have observed only transgranular fractures. This difference may influence the respective interpretations of the TME mechanism. Also, studies have been made using controlled impurity and composition alloys or commercial alloys, and the factors that cause TME may differ for these two types of alloys.

The earlier studies of TME noted that embrittlement coincided with the initiation of cementite precipitation (Ref 115). Such low-temperature precipitated cementite is long and platelike and is present at the grain boundaries. Therefore, the shape and location of the cementite produced at low tempering temperatures was cited as the cause of TME (Ref 116).

The emphasis then shifted to the study of the influence of impurity elements, chiefly phosphorus (which segregates to the prior-austenite grain boundaries during austenitization). This shift was brought about by the observation that TME did not occur in high-purity steels but did occur in steels containing elements such as phosphorus (Ref 117, 118). Nitrogen was also observed to cause embrittlement, as were large amounts of manganese and silicon.

After these developments, several studies suggested that impurities segregated to prior-austenite grain boundaries and cementite precipitation along grain boundaries were both required for TME. The segregation of impurities was seen as a necessity; cementite precipitation was cited as an important factor, but not one that would cause TME by itself (Ref 120, 121, 122). At about the same time, transmission electron microscopy showed that martensite in as-quenched medium-carbon alloy steels has small amounts of retained austenite films present between the laths. Several studies attributed TME to the decomposition of interlath-retained austenite to interlath cementite. It was suggested that alloying elements that promote the decomposition of retained austenite to cementite at lower temperatures, such as manganese and chromium, enhance TME, while alloying elements that do not promote austenite decomposition at low temperatures, such as silicon, nickel, and aluminum, shift TME to higher temperatures. Most of these studies exhibited transgranular test fractures of controlled-composition alloys.

Other studies have observed cementite precipitation from interlath-retained austenite but have described a more complex process for TME. For example, a study of TME in AISI 4340 and 300 M alloy steels stated that the magnitude of TME increased significantly when the volume fraction of interlath-retained austenite was high. A partial decomposition of the retained austenite to interlath cementite upon tempering was observed. Subsequent deformation during testing transformed the balance of the retained austenite that became destabilized because of the depletion of carbon during cementite precipitation. The study further concluded that the segregation of impurity elements at the prior-austenite grain boundaries contributes to the embrittlement process by providing an alternative weak path for fracture to follow. The study thus accounted for either transgranular or intergranular fracture modes.

The concept that a dual role played by interlath carbides is the primary problem and impurity segregation is a secondary influence has been verified by others (Ref 128, 129, 130). In an evaluation of TME in AISI 4340 containing 0.003 and 0.03% P, both steels exhibited TME (Ref 128). For the low-phosphorus steel, interlath cementite initiated cleavage across the martensite laths, while for the high-phosphorus steel, intergranular fracture resulted from the combined influence of carbide formation and phosphorus segregation. However, the plane-strain fracture toughness test results displayed TME only in the high-phosphorus steel; the Charpy V-notch results, on the other hand, showed TME in both steels. A study of AISI 4340 steel observed intergranular fractures in specimens with various levels of manganese, silicon, phosphorus, and sulfur. These fractures were attributed to carbide precipitation and impurity segregation at the prior-austenite grain boundaries (Ref 129). Another study of 4340 found substantial intergranular fracture only after a 350 °C (660 °F) temper (Ref 130). Cementite begins to precipitate at 250 °C (480 °F). With higher tempering temperatures, the number of precipitated carbides increases, and their thickness and length increase. Phosphorus segregates to the prior-austenite grain boundaries during austenitization but does not diffuse during these low-temperature tempering treatments. This study showed that the initial drop in impact energy with tempering at 250 to 300 °C (480 to 570 °F) was caused by the influence of cementite. However, with tempering at 350 °C (660 °F), the amount and size of the cementite at the grain boundaries was sufficient to cause intergranular fracture at the grain boundaries that were already weakened by the presence of impurities.

Instrumented Charpy V-notch testing of AISI 4130 alloy steel containing 0.002 and 0.02% P showed similar losses in impact energy for both steels when tempered in the critical region (Ref 131). As would be expected, the higher-phosphorus steel had lower impact strength at all tempering temperatures. However, the fractures were all transgranular,

irrespective of phosphorus content or tempering temperature. The pre-maximum-load energy decrease with increasing tempering temperature in the range of 200 to 400 °C (390 to 750 °F) was attributed to a change in the work-hardening rate.

A recent study of TME in Fe-0.25C-10Cr-base martensitic steels concluded that TME was not due to the decomposition of interlath-retained austenite (Ref 132). This study instead suggested that TME was the result of the coarsening of interlath and intralath carbides.

As this review has shown, our understanding of tempered martensite embrittlement is not complete. Fractures of test specimens tempered within the critical region do vary with transgranular fractures observed with tempering between 200 and 300 °C (390 and 570 °F), and intergranular fractures usually, but not always, observed with tempering at about 350 °C (660 °F). These differences may be due to differences in carbon, alloy, and impurity content, as well as in strength level, test temperature, nature of the test, and grain size. Impurities appear to influence coarse-grain steels to a greater degree than fine-grain steels.

Sensitization

Austenitic stainless steels become susceptible to intergranular corrosion when subjected to temperatures in the range of 480 to 815 °C (900 to 1500 °F), generally from welding or service conditions. This susceptibility has been termed sensitization and has been attributed to the precipitation of $M_{23}C_6$ carbides on the austenite grain boundaries. The mechanism for sensitization was initially proposed as being due to the depletion of chromium at the grain boundaries when the carbides form (Ref 133, 134). The chromium content adjacent to the grain-boundary carbides was thought to drop below some critical limit, which rendered the alloy susceptible to severe localized attack by the corrosive environment.

This theory for the sensitization mechanism was widely accepted, and considerable indirect evidence for its validity was subsequently developed. However, when the electron microprobe was developed in the 1950s and researchers tried to detect the impoverished chromium zone, they were unable to do so (Ref 135, 136), or they could show chromium depletion only when the steel was carburized (Ref 137), or they detected only small regions of possible chromium depletion (Ref 138). Therefore, it was concluded that if such a zone exists, it must be less than 1 μm wide (40 $\mu\text{in.}$) and the concentration gradient must be rather steep. This prompted a number of other theories to be developed to explain sensitization, for example, electrochemical consideration of the nobility of the carbides (Ref 139, 140), strains at the carbide/austenite interface (Ref 139), and grain-boundary strain energy acting as the driving force for intergranular attack (Ref 141).

The picture was further complicated by a number of observations of intergranular corrosion in austenitic stainless steels under conditions unfavorable for sensitization, and in nonsensitized stainless steels with no detectable grain-boundary precipitation (Ref 142, 143, 144, 145, 146, 147, 148, 149). The latter occurred in highly oxidizing solution, such as the nitric dichromate solution. Because of these difficulties, attention was focused on the influence of impurity elements, such as phosphorus, that are segregated to the austenite grain boundaries. It was subsequently proposed that intergranular corrosion of austenitic stainless steels was due to the presence of a continuous grain-boundary path of either carbides or solute segregated regions (Ref 142). Direct evidence for impurity segregation, chiefly of phosphorus, has been obtained from intergranular fracture surfaces of both sensitized and nonsensitized austenitic stainless steels (Ref 148, 149, 150, 151, 152).

The development of scanning transmission electron microscopes (STEM) with electron beam sizes of about 10 nm (100 Å) in diameter, coupled with energy-dispersive x-ray analysis, has provided direct proof of chromium depletion due to carbide precipitation at the grain boundaries (Ref 153, 154, 155, 156, 157, 158, 159). These studies have demonstrated that significant chromium depletion occurs after sensitization at grain boundaries adjacent to precipitated carbides. For equal times, the degree of chromium depletion for T316LN was greater with aging at 650 °C (1200 °F) than at 700 °C (1290 °F). Increasing the holding time caused the width of the depleted zone to increase. The width of chromium depletion along the grain boundaries around individual carbides was much greater than the width of the depletion zone into the grain interior (~3 μm , or 120 $\mu\text{in.}$, versus ~0.15 μm , or 6 $\mu\text{in.}$, for samples aged 100 h at 700 °C, or 1290 °F) (Ref 156). Evidence of molybdenum depletion has also been obtained. These direct measurements are in relative agreement with theoretical calculations of chromium levels in equilibrium with growing carbides during sensitization (Ref 160, 161, 162, 163) and with empirical modifications of such theories (Ref 164).

Transmission electron microscopy studies of the precipitated carbides have demonstrated that the susceptibility to intergranular corrosion with sensitization temperature and time correlates well with the morphology of the grain-boundary carbide precipitates (Ref 165, 166, 167, 168, 169). These studies have demonstrated that the grain-boundary precipitate due to sensitization is always $(\text{Cr,Fe})_{23}\text{C}_6$, that is, $M_{23}C_6$ carbide. The preferred sites for the nucleation of $M_{23}C_6$ are, in decreasing order of occurrence (Ref 166):

- Delta ferrite-austenite phase boundaries
- Austenite grain boundaries
- Incoherent twin boundaries
- Coherent twin boundaries

The carbides grow in the plane of the grain or twin boundaries. The morphology of the precipitated $M_{23}C_6$ depends on the type of boundary where precipitation occurs and the temperature (Ref 166). Precipitates that form at δ -ferrite-austenite phase boundaries or at austenite grain boundaries are dendritic or geometric in shape; the shape depends on the boundary orientation and misfit between the grains, the temperature, and the time at temperature. Those that form at incoherent twin boundaries look like ribbons of connected trapezoids while those that form at coherent twin boundaries have an equilateral thin triangular shape. Grain-boundary precipitates are classified into three categories:

- Dendritic shapes
- Separate geometric shapes
- Sheets of interconnected geometric particles

The sheets form at the lower temperatures; dendrites form at higher temperatures within the sensitization range, and the small, isolated geometric particles can form over the entire sensitization range and above, up to about 980 °C (1800 °F) (Ref 166). Sensitization is most severe for specimens sensitized at temperatures in the lower portion of the range where sheets of interconnected geometrically shaped carbides are formed. It is well known that healing occurs very long times in the sensitization range; that is, long holding times result in reduced chromium depletion and reduced intergranular attack. When this occurs, the sheets of interconnected particles gradually separate into arrays of thick geometric particles (Ref 166).

Several approaches have been taken to minimize or prevent the sensitization of austenitic stainless steels. If sensitization results from welding heat and the component is small enough, solution annealing will dissolve the precipitates and restore immunity. However, in many cases this cannot be done because of distortion problems or the size of the component. In these cases, a low-carbon version of the grade or a stabilized composition should be used. Complete immunity requires a carbon content below about 0.015 to 0.02% (Ref 170). Additions of niobium or titanium to tie up the carbon are also effective in preventing sensitization as long as the ratio of these elements to the carbon content is high enough. Stabilizing heat treatments aimed at producing intergranular carbides are not very effective.

Few studies have been conducted on the influence of sensitization on mechanical properties. In general, carbide precipitation produces a slight increase in tensile strength and a minor reduction in tensile ductility (Ref 134). Heats of AISI 304 containing various levels of phosphorus and sulfur after sensitization were tested using half-size Charpy V-notch specimens fractured at liquid nitrogen temperature. Longitudinally oriented specimens were sensitized at 550 to 850 °C (1020 to 1560 °F) for 15 to 105 min. The decrease in impact energy, relative to the results before sensitization, were much greater in phosphorus-doped steels than in sulfur-doped steels. Fractures were intergranular for the phosphorus-doped steels and transgranular for the sulfur-doped steels. Figure 29 shows the reduction in half-size Charpy V-notch impact energy for phosphorus-doped steels aged at different temperatures for 5100 s (85 min); the specimens were tested after cooling in liquid nitrogen. For heats 1 and 6, embrittlement was greatest at 750 °C (1380 °F); somewhat higher or lower temperatures produced near-normal toughness. Embrittlement was greater for high-phosphorus heats, but these levels are greater than those encountered in commercial heats. The loss in toughness for the phosphorus-doped heats increased with holding times at temperatures between 650 and 825 °C (1200 and 1515 °F); somewhat higher or lower temperatures again produced near-normal toughness. The modified Strauss test produced higher corrosion rates for heats sensitized at 650 °C (1200 °F), and the corrosion rate increased linearly with increasing time and increasing impurity content.

Fig. 29 Influence of phosphorus content and aging temperature on the relative loss in Charpy impact energy (tested using half-size specimens broken after cooling in liquid nitrogen) for sensitized AISI 304 stainless steel. Sensitization time, 5100 s. Source: Ref 171

Ferritic Stainless Steels. Sensitization and intergranular corrosion also occur in ferritic stainless steels (Ref 172, 173, 174, 175, 176, 177, 178). A wider range of corrosive environments can produce intergranular attack in ferritic grades than is the case for austenitic grades. In the case of welds, the attacked region is usually larger for ferritic grades than for austenitic grades because temperatures above 925 °C (1700 °F) are involved in causing sensitization. Ferritic grades with less than 15% Cr are not susceptible, however. One study demonstrated that ferritic grades with 16 to 28% Cr were susceptible to intergranular corrosion when rapidly cooled from above 925 °C (1700 °F). This susceptibility was due to solution of carbides and nitrides followed by their reprecipitation in the grain boundaries. Subsequent annealing at 650 to 815 °C (1200 to 1500 °F) restored corrosion resistance (Ref 172). Therefore, the thermal processes causing intergranular corrosion in ferritic stainless steels are different from those for austenitic stainless steels. Reducing the carbon and nitrogen interstitial levels improves the intergranular corrosion resistance of ferritic stainless steels.

Sensitization can occur in titanium-stabilized ferritic stainless steels (Ref 177, 178). The thermal treatment that causes sensitization, however, is altered by the addition of titanium. First, high-temperature exposure requires a temperature in excess of 1050 °C (1920 °F) to dissolve the Ti(C,N) that reprecipitates upon cooling, even with water, forming grain-boundary precipitates of (Ti,Cr)(C,N) (Ref 177). The chromium-to-titanium (Cr/Ti) ratio in these precipitates is

approximately $\frac{1}{3}$. Aging at 480 to 550 °C (895 to 1020 °F) causes these precipitates to grow, and the Cr/Ti ratio increases to approximately $\frac{1}{2}$. This depletes the grain-boundary zone around the precipitates of chromium, thereby increasing the susceptibility to intergranular corrosion. Again, long times at 480 to 550 °C (895 to 1020 °F) reduce the chromium gradient around the particles and restore corrosion resistance. Aging above 600 °C (1110 °F) also produces resistance to intergranular corrosion because the chromium in the (Ti,Cr)(C,N) precipitates is replaced by titanium, that is, the Cr/Ti ratio decreases. A titanium-stabilized 12% Cr ferritic grade was also found to sensitize under similar heat treatment conditions (Ref 178).

Duplex stainless steels are resistant to intergranular corrosion when aged in the region of 480 to 700 °C (895 to 1290 °F). It has been recognized for some time that duplex grades with 20 to 40 vol% ferrite exhibit excellent resistance to intergranular corrosion (Ref 179). A study of intergranular corrosion in AISI 308 stainless steel that was heat treated to produce 15% ferrite found that aging at 600 °C (1100 °F) caused the precipitation of $M_{23}C_6$ at austenite-ferrite boundaries (Ref 180). When this occurs, most of the chromium in the $M_{23}C_6$ comes from the ferrite grains; only a very small amount comes from the austenite grains. A chromium-depleted zone is formed at the austenite/carbide interface, which is very narrow, compared to those in fully austenitic sensitized stainless steels. Aging for 7 h at 600 °C (1110 °F) replenished the chromium-depleted zone and stopped the localized intergranular attack (ASTM A 262E test). Therefore, the healing of depleted zones is much more rapid in duplex grades.

The aging of duplex stainless steels produces a variety of phases in the ferrite (Ref 180). Aging at 480 °C (895 °F) does not produce $M_{23}C_6$, but it will produce an extremely small, finely distributed, chromium-rich α' phase in the ferrite. Aging at 600 to 700 °C (1110 to 1290 °F) produces a complex series of transformations of the ferrite phase.

Another study of AISI 308 showed that for a given carbon content there is a critical amount and distribution of the ferrite/austenite interfacial boundary area (Ref 181). Above this critical level, the alloy is immune to intergranular corrosion with aging between 480 and 700 ° (895 and 1290 °F) for up to 1000 h. If the amount and distribution of these boundaries is below the critical level, two types of sensitization behavior can occur. The amount and distribution of the ferrite/austenite interfaces may be adequate to produce the rapid healing of chromium-depleted regions that form at the austenite/carbide interface during aging. If not, the alloy will behave as a fully austenitic grade. Additional information on austenitic, ferritic, and duplex stainless steels is available in the articles "Wrought Stainless Steels" and "Cast Stainless Steels" in this Volume.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

475 °C Embrittlement

Iron-chromium alloys containing 13 to 90% Cr are susceptible to embrittlement when held within or cooled slowly through the temperature range of 550 to 400 °C (1020 to 750 °F). This phenomenon has been called 475 °C (885 °F) embrittlement and it produces an increase in tensile strength and hardness and a decrease in tensile ductility, impact strength, electrical resistivity, and corrosion resistance (Ref 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203). Microstructure effects are minor: Grain boundaries etch more widely, and the grain interiors darken.

Numerous theories have been proposed to account for 475 °C embrittlement. The problem occurs with iron-chromium ferritic and duplex ferritic-austenitic stainless steels, and not with austenitic grades. The earliest theories suggested that embrittlement was due to precipitation of second phases such as phosphides (Ref 183), carbides or nitrides (Ref 184), or oxides (Ref 188). Others suggested that embrittlement was due to σ phase, which does form in iron-chromium alloys, or some transitional phase that precedes σ formation (Ref 185, 186, 187). However, σ forms at higher temperatures and has never been detected in 475 °C embrittled specimens. Japanese researchers (Ref 189, 190) suggested that 475 °C

embrittlement was due to ordering, that is, from the formation of Fe_3Cr , FeCr , and FeCr_3 superlattices. However, subsequent experiments using neutron diffraction failed to detect evidence of ordering.

A 1953 study using transmission electron microscopy observed that 475 °C embrittlement caused the precipitation of a coherent chromium-rich bcc phase with a lattice parameter only slightly greater than the iron-rich bcc ferritic matrix phase.

These precipitates were extremely small, for example, about 15 to 30 nm (150 to 300 Å) in diameter for an Fe-27% Cr alloy aged from 10,000 to 34,000 h at 480 °C (900 °F). The precipitates were nonmagnetic and contained about 80% Cr. The rate of growth of the precipitates was very slow, and they did not appear to over age (Ref 191). Other studies have confirmed these findings (Ref 192, 193, 194, 195, 196, 197, 198, 199). The 1953 study was unable to explain its observations based on the existing iron-chromium phase diagram. Later work (Ref 192) concluded that 475 °C embrittlement was a precipitation-hardening phenomenon resulting from the presence of a miscibility gap in the iron-chromium system below 600 °C (1110 °F). The location of the miscibility gap was later refined (Ref 200).

Aging at 475 °C (885 °F) has been shown to cause a rapid rate of hardening with aging between about 20 and 120 h because of homogeneous precipitation. The rate of hardening is much slower with continued aging from 120 to 1000 h. During this aging period, the precipitates grow. Aging beyond 1000 h produces little increase in hardness because of the stability of the precipitates, which do not grow larger than about 30 nm (300 Å).

Precipitation of the chromium-rich α' phase in iron-chromium alloys can occur either by spinodal decomposition or by nucleation and growth, depending on the aging temperature and alloy composition. For example, an Fe-30% Cr alloy will decompose to chromium-rich precipitates in an iron-rich matrix (chromium-depleted) inside the spinodal at 475 °C (885 °F), forming spherical α' , or outside the spinodal at 550 °C (1020 °F), forming disk-shaped α' (Ref 196). An Fe-20Cr alloy will decompose by nucleation and growth at 470 °C (880 °F), while Fe-30Cr, Fe-40Cr, and Fe-50Cr alloys will decompose spinodally at 470 °C (880 °F).

Even for a severely embrittled alloy, 475 °C embrittlement is reversible. Properties can be restored within minutes by reheating the alloy to 675 °C (1250 °F) or above (Ref 188, 194). The degree of embrittlement increases with chromium content; however, embrittlement is negligible below 13% Cr. Carbide-forming alloying additions, such as molybdenum, vanadium, titanium, and niobium, appear to increase embrittlement, particularly with higher chromium levels. Increased levels of carbon and nitrogen also enhance embrittlement and, of course, are detrimental to nonembrittled properties as well. Cold work prior to 475 °C (885 °F) exposure accelerates embrittlement, particularly for higher-chromium alloys.

Figure 30 demonstrates the C-curve nature of the increase in hardness due to aging for an Fe-30% Cr ferritic stainless steel (Ref 192). The nose of the curve decreases with time. Figure 31 shows the results for aging at 475 °C (885 °F) for up to 1000 h for iron-chromium alloys with 15, 20.6, 23, 37, and 56% Cr. As the chromium content increased, the time to the initial increase in hardness decreased. Over 200 h were required for the 15% Cr alloy, only about 4 h for the 20.6% Cr alloy, and less than 1 h for the 23% Cr alloy. The initial increase in hardness was nearly instantaneous for the 37 and 56% Cr alloys. Accompanying the increase in hardness with aging at 475 °C (885 °F) are an increase in tensile and yield strength and a decrease in tensile ductility and impact energy. Examples of such data can be found in Ref 185, 186, 199, 201, 202, 203

Fig. 30 Time-temperature-constant hardness curves for Fe-30Cr (Alloy 90) after aging done between approximately 430 and 540 °C (805 and 1005 °F), around the region of 475 °C embrittlement. Specimens rolled at 900 °C (1650 °F); starting hardness, 195 to 205 HV. Source: Ref 192

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Sigma Phase Embrittlement

The existence of σ phase in iron-chromium alloys was first detected in 1907 by the observation of a thermal arrest in cooling curves (Ref 204). It was suggested that the thermal arrest could be due to the formation of an FeCr intermetallic compound. The first actual observation of σ in iron-chromium alloys was reported in 1927 (Ref 205). The phase was referred to as the brittle constituent (B constituent) and was reported to be corundum hard. In a discussion of this paper, it was suggested that the B constituent was the FeCr intermetallic phase detected in 1907. The σ phase was identified by x-ray diffraction in 1927 (Ref 206) and in 1931 (Ref 207). Numerous earlier investigators, however, had failed to detect the presence of σ ; this failure caused considerable confusion.

After the existence of σ was firmly established, numerous studies were conducted to define the compositions and temperatures over which σ could be formed. This produced a series of refinements to the iron-chromium equilibrium diagram, as in the case of 475 °C embrittlement. Successive studies demonstrated that σ could form in alloys with lower and lower chromium contents under the proper conditions; one study demonstrated the formation of σ at 480 °C (900 °F) in an alloy with less than 12% Cr. In general, σ forms with long-time exposure in the range of 565 to 980 °C (1050 to 1800 °F), although this range varies somewhat with composition and processing. Sigma formation exhibits C-curve behavior with the shortest time for formation (nose) generally occurring between about 700 and 810 °C (1290 and 1490 °F); the temperature that produces the greatest amount of σ with time is usually somewhat lower.

The general characteristics of σ phase have been reviewed extensively (Ref 209, 210, 211, 212, 213, 214, 215, 216). The name sigma stems from work done in 1936 (Ref 217). Sigma-type phases have since been identified in over fifty binary systems and in other commercial alloys (for example, nickel-base superalloys). Sigma phase has a tetragonal crystal structure with 30 atoms per unit cell and a c/a ratio of approximately 0.52 (Ref 216). Sigma in iron-chromium alloys has a hardness equivalent to approximately 68 HRC (940 HV). Because of its brittleness, σ often fractures during indentation. At room temperature, σ is nonmagnetic. Embrittlement effects due to σ are greatest at room temperature.

Austenitic and Ferritic Stainless Steels. In commercial alloys, silicon, even in small amounts, markedly accelerates the formation of σ . In general, all of the elements that stabilize ferrite promote σ formation. Molybdenum has an effect similar to that of silicon; aluminum has a lesser influence. Increasing the chromium content, of course, also favors σ formation. Small amounts of nickel and manganese also increase the rate of σ formation, although large amounts, which stabilize austenite, retard σ formation. Carbon additions decrease σ formation by forming chromium carbides, thereby reducing the amount of chromium in solid solution. Additions of tungsten, vanadium, titanium, and niobium also promote σ formation. As might be expected, σ forms more readily in ferritic than in austenitic stainless steels. Coarse grain sizes from high solution-annealing temperatures retard σ formation, and prior cold working enhances it. The influence of cold work on σ formation depends on the amount of cold work and its effect on recrystallization. If the amount of cold work is sufficient to produce recrystallization at the service temperature, σ formation is enhanced. If recrystallization does not occur, the rate of σ formation may not be affected. Small amounts of cold work that do not promote recrystallization may actually retard σ formation (Ref 218).

The composition of σ in austenitic stainless steels is more complex than it is for simple iron-chromium ferritic grades. Several studies, particularly for AISI 316, have analyzed the composition of σ . These studies have used a traditional wet chemical analysis of bulk-extracted σ , wavelength-dispersive spectroscopy (WDS) with an electron microprobe, or energy-dispersive spectroscopy (EDS) with either a scanning transmission electron microscope (for thin foils) or a scanning electron microscope (SEM) (for bulk specimens) (Ref 219).

An analysis of σ in AISI 316 by the SEM-EDS approach obtained a composition of 11Mo-29Cr-55Fe-5Ni in a specimen aged 3000 h at 815 °C (1550 °F) (Ref 220). A WDS analysis using the electron microprobe of AISI 316 heated 60 h at 870 °C (1600 °F) obtained a σ composition of 26.4Cr-3.3Ni-53.7Fe-8.5Mo (Ref 221). An analysis of σ in a failed AISI 316 superheater tube using STEM-EDS of thin foils obtained a composition of 52.7Fe-37Cr-3.7Mo-4.8Ni-0.7Si-0.4Mn (average of several results).

Reference 223 presents an analysis of σ in three versions of AISI 310 (a standard version, a low-carbon version, and a high silicon version) and titanium-stabilized AISI 316. The analysis was done using the electron microprobe. For the low-carbon AISI 310S, the chromium-to-iron (Cr/Fe) ratio in σ was constant and equal to 1 for all temperatures and times; the composition was 46Cr-46Fe-8Ni. For the AISI 310 and AISI 310Si, the composition of σ varied with temperature and time, and the Cr/Fe ratio of 1 was obtained after a certain time at any temperature used. The higher the temperature, the shorter the time required to obtain a Cr/Fe ratio of one. When the Cr/Fe ratio stabilized at 1 for 310 and 310Si, σ had the same composition as in the low-carbon version. The work with 316Ti showed that the molybdenum content in σ increased with temperature. As the molybdenum content in σ increased, the iron content increased, and the chromium and nickel contents decreased. The (Cr+Mo)/(Fe+Ni) ratio was constant, and the formula for σ was expressed as (Cr,Mo)₃₅(Fe,Ni)₆₅.

Although the chemical composition of σ varied with temperature and time, the c/a ratio of the tetragonal unit cell was constant at 0.519.

The influence of molybdenum, which is known to promote σ formation, was examined using wrought 25Cr-20Ni alloys with additions of up to 8.2% Mo (Ref 224). Sigma was analyzed with the electron microprobe using specimens aged at 850 °C (1560 °F) for 525 h (the 8.2% Mo specimen was aged for 350 h). As the molybdenum content in the 25Cr-20Ni alloys increased to 8.2%, the chromium content in σ decreased from 42.6 to 31.0%, the iron content decreased from 43.3 to 38.8%, the nickel content remained constant at about 10%, and the molybdenum content increased to 14.3%. In addition, as the molybdenum content of the steel increased, the volume fraction of σ increased from 3 to 60% for these aging treatments.

Sigma formation in pure iron-chromium alloys is rather sluggish, which accounts for much of the confusion in early studies concerning its existence. Subsequent work showed that the formation of σ dramatically accelerated by prior cold work and by silicon additions (Ref 217). In ferritic stainless steels, the addition of even minor amounts of other alloying elements expands the compositional range over which σ may form and increases the rate of formation. All of the ferritic stabilizing elements promote σ formation.

Sigma will also form austenitic alloys. In fully austenitic alloys, σ forms from the austenite along grain boundaries. If δ -ferrite is present in the austenitic alloy, σ formation is more rapid and occurs in the δ -ferrite. Sigma will form more readily in austenitic alloys containing additions of ferrite-stabilizing elements such as molybdenum and titanium; the rate of formation can be quite rapid in these alloys.

The most sensitive room-temperature property for assessing the influence of σ is the impact strength. A study of the influence of σ on the toughness of AISI 310 shows the dramatic loss in toughness due to σ (Fig. 32). With increasing time at temperature, particularly in the range of 760 to 870 °C (1400 to 1600 °F), the toughness decreased by about 85%.

Fig. 32 Influence of aging time and temperature on the room-temperature impact energy of an Fe-25Cr-20Ni alloy. Annealed value, 89J (66 ft · lbf). Source: Ref 225

The influence of high-temperature exposure on the toughness of a low-interstitial 29Cr-4Mo ferritic stainless steel has been examined (Ref 226). Figure 33 shows the room-temperature impact strength trends for this alloy as a function of aging temperature and time. Aging at 371 °C (700 °F) produced no loss in toughness. However, aging at 427, 482, and 538 °C (800, 900, and 1000 °F), in the range of 475 °C embrittlement, produced a loss of toughness that was most pronounced at 482 °C (900 °F). Aging at higher temperatures, where σ was formed, produced more pronounced embrittlement, which was greatest at 816 °C (1500 °F). Figure 34, which is a summary is a summary of this data, shows the time at aging temperatures between 371 and 978 °C (700 and 1790 °F) required to produce a DBTT of 25 and 100 °C (77 and 212 °F). This produces a C-curve presentation of the time for embrittlement as a function of aging temperature. For σ formation, embrittlement was most rapid at about 775 °C (1425 °F); 475 °C embrittlement was slower with a maximum rate at about 480 °C (900 °F). Chi phase was also observed, along with σ , after aging in the high-temperature range. Sigma formed over the range of 595 to 925 °C (1100 to 1700 °F). Embrittlement was most pronounced when intergranular σ films formed, producing intergranular tensile and impact fractures.

Fig. 34 Time-temperature relationships to produce 25 and 100 °C (75 and 212 °F) DBTTs for a 29Cr-4Mo ferritic stainless steel as a function of aging times that cover both the 475 °C (885 °F) embrittlement range and the σ phase embrittlement range. Source: Ref 226

While some studies have demonstrated only a minor increase in hardness and strength because of σ formation, studies of some steels have demonstrated more substantial changes. Tensile ductility, like toughness, is generally substantially reduced. One study has demonstrated that high-chromium σ -hardenable alloys are useful in applications involving high-temperature erosion or wear, for example, exhaust valves (Ref 227). Such steels generally contain from 20 to 30% Cr, about 0.25 to 0.45% C, and additions of manganese and nickel to produce a duplex structure; they also generally contain additions of elements that promote σ formation, such as silicon and molybdenum. Such steels can be hardened to about 40 HRC by σ and retain their strength at high temperatures. Although the toughness of such steels is reduced about 35% by the presence of σ , they do perform well as long as the extent of σ -phase embrittlement is not severe. The toughness and ductility of σ -containing steels at high temperatures is considerably better than at room temperature; however, such steels are not useful at high temperatures if shock resistance is required.

An examination of the high-temperature properties of a 25Cr-20Ni-2Si (type 314) austenitic stainless steel aged between 650 and 980 °C (1200 and 1800 °F) showed that with the proper amount and distribution of σ , substantial increases in yield and tensile strengths results for test temperatures up to 760 °C (1400 °F) (Ref 228). For conditions involving slow strain rates, σ phase reduces creep resistance. Variations in austenite grain size, however, can exert an even greater effect on high-temperature tensile and creep properties. Fine grain sizes increase short-time high-temperature tensile strength but reduce long-time creep strength. The room-temperature ductility of these alloys is poor but is restored at temperatures above 540 to 650 °C (1000 to 1200 °F). A fine distribution of σ is detrimental to creep strength but minimizes loss of ductility at room temperature. Sigma has also been found to be detrimental in thermal-fatigue situations (Ref 229). High-temperature exposure can produce a variety of phases, and embrittlement is not always due solely to σ formation (Ref 230). Therefore, each situation must be carefully evaluated to determine the true cause of the degradation of properties.

Duplex Stainless Steels. Sigma phase is known to form quite rapidly in duplex stainless steels. One study, for example, observed σ after 15 min at 750 °C (1380 °F) and 2 min at 850 °C (1560 °F) in a 20Cr-10Ni-3Mo duplex alloy (Ref 231). Another study found that σ formed after 2 min at 900 °C (1650 °F) in a 21Cr-7Ni-2.4Mo-1.3Cu (UNS S32404) duplex stainless steel containing 33% ferrite (Ref 232). Sigma formed in a C-curve manner along with a number of other phases, but sigma was the worst embrittler and led to massive pit initiation in corrosion tests, Sigma formed in the ferrite, and pitting occurred in the chromium-molybdenum-depleted ferrite- σ regions.

An evaluation of the effects of alloying elements on σ formation in duplex stainless steels found that increasing chromium and molybdenum contents caused an increase in the rate of σ formation and in the maximum amount produced (Ref 233). Increasing the nickel content decreased the maximum amount of σ that could form but increased the rate of σ formation. Sigma formation occurred primarily by the decomposition of ferrite into σ and austenite.

The influence of σ on corrosion characteristics is rather complex. In many instances, little influence is observed in environments normally used with a particular alloy. Large σ particles appear to be rather harmless; a fine distribution of particles, particularly if present at the grain boundaries and in highly oxidizing solutions, is more harmful.

Hydrogen Damage

Of all the embrittlement problems discussed in this article, that due to hydrogen is the most widespread and influences the behavior and properties of nearly all ferrous alloys and many other metals. Indeed, the ubiquitous nature of hydrogen and the wide variety of forms of damage that it can produce make this subject difficult to address and summarize. Hydrogen can come from many sources. It can be retained in the steel:

- Upon solidification (supersaturated)
- From acid cleaning (pickling)
- For electroplating
- From contact with water or other hydrogen-containing liquids or gases
- From pure hydrogen gas

Hydrogen has no known beneficial effects on iron and steel, only detrimental effects. While the influence of hydrogen on high-strength steels is well known, even the softest irons are not immune from hydrogen damage.

Despite the thousands of research articles published on this subject, there is still a great deal that is not fully understood and considerable controversy over the mechanisms by which hydrogen exerts influence. The damage produced by hydrogen has been known since at least 1875 (Ref 234).

The general term hydrogen damage has been used to be consistent with a phenomenological classification scheme covering the various hydrogen degradation processes (Ref 235, 236). Hydrogen can cause a wide variety of problems, and it is helpful to categorize them (Table 1). Other reviews on hydrogen damage can be found in Ref 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, and 251.

Hydrogen environmental embrittlement, hydrogen stress cracking, and loss of tensile ductility are grouped under hydrogen embrittlement. Hydrogen environmental embrittlement refers to the degradation of mechanical properties in metals such as steels when they are deformed in a hydrogen-containing environment. Degradation is enhanced by slow strain rates and high hydrogen pressures.

Hydrogen stress cracking is characterized by the brittle fracture of an alloy that is normally ductile while being stressed below its yield strength in a hydrogen-containing environment. This problem is also called "static fatigue" and hydrogen-induced cracking. In general, there is a certain stress level (threshold) below which such cracking does not occur. Hydrogen stress cracking involves the absorption of hydrogen, followed by hydrogen diffusion to highly stressed regions, particularly those associated with notches. Thus, there is a delay time, or incubation time, before cracking occurs. H_2S stress cracking is a specific type of hydrogen stress cracking.

The loss of tensile ductility, one of the oldest forms of hydrogen damage, occurs in steels and other alloys exposed to hydrogen. It generally affects lower-strength alloys. Fracture does not occur, as it does with higher-strength alloys; these alloys experience only a decrease in tensile elongation and reduction in area. The phenomenon is sensitive to strain rate and hydrogen content. It is increased by decreases in strain rate and increases in hydrogen.

Hydrogen Environmental Embrittlement

Hydrogen attack occurs at high temperatures rather than at or near room temperature. Hydrogen reacts with carbon within the steel to form methane gas. This may simply decarburize the steel, lowering its strength, or may produce cracks or fissures. This problem does not occur below 200 °C (390 °F). Blistering is observed in low-strength steels and other metals. It is caused by atomic hydrogen diffusing to internal defects or inclusions where it precipitates as molecular (diatomic) hydrogen. This generates substantial pressure, which produces blisters. Shatter cracks, flakes, and fisheyes are terms that describe cracks or the surface appearance of a fracture in castings, forgings, wrought alloys, or weldments. These defects are caused by the presence of excessive hydrogen in the liquid melt prior to solidification. The solubility of hydrogen in the melt is much greater than after solidification; cracking can result if the hydrogen level is above a critical level and is not permitted to diffuse out of the material before cooling to ambient temperature. Microperforation occurs mainly when steels are exposed to very high-pressure hydrogen near room temperature. As the term implies, small fissures are formed in the metal. A degradation in flow properties occurs in steels at room temperature. Metal hydride formation does not occur in steels, but is a problem in metals such as titanium, niobium, and zirconium.

The fact that hydrogen embrittlement increases with decreasing strain rate and increasing temperature above ambient, as well as the fact that these are mutually dependent variables, is directly opposite to the general trend for bcc metals that undergo a ductile-to-brittle transition behavior with increasing strain rate and decreasing temperature below ambient. This unique behavior arises because the phenomenon is controlled by the diffusion of hydrogen through the lattice. Hydrogen effects are further complicated by the chemical analytical limitations associated with hydrogen analyses. Although a bulk hydrogen analysis can be made, hydrogen in the lattice cannot be differentiated from hydrogen within voids or traps.

Figure 35 demonstrates the influence of hydrogen on the tensile reduction of area as a function of strength level (Ref 237). The AISI 4340 specimens, quenched and tempered to three different strength levels, were electrolytically charged with hydrogen using an aqueous 4% H_2SO_4 solution. Charging times were selected that lowered the tensile ductility, but not to 0. Figure 35 shows that with increasing charging time, that is, with increased hydrogen pickup, the reduction of area decreased. As the tensile strength increased, the same degree of charging had a greater influence on decreasing the reduction in area.

Fig. 35 Effect of charging time on the tensile reduction in area of AISI 4340 steel quenched and tempered to different strength levels. Source: Ref 237

Hydrogen embrittlement, in classic form, is reversible in that the damage should be eliminated by removing the hydrogen. However, hydrogen can also cause permanent damage. Figure 36 shows the recovery of tensile reduction in area for AISI 4340 specimens charged for 5 min and then aged for various times at room temperature before tensile testing (Ref 237). For all three strength levels (the same strength levels in Fig. 35), the tensile ductility returned to normal levels with time. About 100 h were required; however, there was no clear trend in recovery time with strength level.

Fig. 36 Effect of aging time on the tensile ductility of heat-treated AISI 4340 at three different strength levels.
Source: Ref 237

Figure 37 shows the combined effects of reversible and permanent damage due to hydrogen (Ref 252). The AISI 1020 carbon steel tensile specimens were tested both uncharged and cathodically charged with hydrogen, and each group was further tested after aging for 20 h at 250 °C (480 °F) in air. Tensile tests were performed over a wide range of temperatures, from -196 °C (-321 °F) (liquid nitrogen temperature) to room temperature. The uncharged specimens, with or without aging, exhibited a gradual decrease in tensile reduction of area with decreasing test temperature, as would be expected. The aging treatment had no influence on the uncharged specimens. The charged specimens that were not aged exhibited much lower tensile ductility from room temperature to -160 °C (-255 °F), where they had about the same ductility as the uncharged specimens. However, at the liquid nitrogen temperature (-196 °C, or -321 °F), the reduction in

area was much lower than that in the uncharged steel. The hydrogen-charged specimens that were aged at 250 °C (480 °F) exhibited the same high ductility as the uncharged specimens down to -160 °C (-255 °F), but at -196 °C (-321 °F) they exhibited the same very low percentage of reduction in area as the non-aged charged specimens. Aging apparently removed the hydrogen that caused the loss of ductility from 20 to -160 °C (70 to -255 °F), but it did not remove the low ductility at -196 °C (-321 °F). Further testing of aged, charged specimens where the surface layer was removed resulted in the same -196 °C (-321 °F) ductility as the uncharged specimens. It was shown that cathodic charging produced blisters and cracks at the surface (permanent damage) that made the charged specimens notch sensitive at -196 °C (-321 °F) whether hydrogen was present or not. The effects of combined reversible and permanent damage caused by hydrogen is difficult to separate, particularly in higher-strength materials.

Fig. 37 Influence of test temperature and reversible versus permanent damage caused by hydrogen charging on the tensile ductility of AISI 1020 steel, with and without aging. Source: Ref 252

Hydrogen Stress Cracking and Loss of Tensile Ductility

Another classic form of hydrogen embrittlement, hydrogen stress cracking (also called "static fatigue" or hydrogen-induced cracking) involves delayed fracture at stresses below the yield strength. Figure 38 illustrates the nature of these failures for high-strength hydrogen-charged steels (Ref 238). The notched tensile strength may be lower than for noncharged specimens. A wide range of applied stresses can cause delayed fractures, with the applied stress having only a minor influence on the time to failure. Below some level of applied stress, fracture does not occur. This critical level of stress is referred to as the "static endurance limit." Additional work has demonstrated that the time between the incubation of cracking and failure decreases with decreasing test temperature until, at -46 °C (-50 °F), they are coincident (Ref 253). Resistivity measurements also showed that crack growth was discontinuous.

Fig. 38 Failure characteristics of a hydrogen-charged high-strength steel. Source: Ref 238

Figure 39 shows test results for hydrogen charged notched specimens of AISI 4340 (cathodically charged 5 min in aqueous 4% H_2SO_4 and then cadmium plated, 25 min) that were aged at 150 °C (300 °F) for various times and then loaded in tension until fracture (Ref 238, 239). The notched tensile strength of the material was 2070 MPa (300 ksi), and the smooth bar tensile strength was the 1585 MPa (230 ksi) before charging and plating. For any aging (baking) time, the time to fracture increased slightly with decreasing load until the critical applied stress at which fracture did not occur was reached. Also, as the aging time increased, the critical stress increased, and the times to fracture at loads above this level increased. With aging at 150 °C (300 °F), the critical stress level increased from 515 MPa (75 ksi) to about 1655 MPa (240 ksi), indicating a recovery brought about by the removal of hydrogen.

Fig. 39 Time to fracture as a function of applied stress and aging (baking) time at 150 °C (300 °F) for notched tensile specimens of AISI 4340 that were hydrogen charged and electroplated with cadmium. Source: Ref 238

Work has been done that demonstrates the combined influence of strain rate and test temperature on the tensile ductility of AISI/SAE 1020 carbon steel (Ref 254, 255). Specimens were tested in tension at strain rates from 0.5 to 19,000 min⁻¹ over the temperature range -196 to 100 °C (-320 to 212 °F). The test specimens were either spheroidize annealed before testing (for uncharged specimens) or cathodically charged. Figure 40 shows the results of these tests. For the uncharged specimens (Fig. 40a), the tensile ductility (natural log of the original cross-sectional area, a_0 , to the final cross-sectional area, a_f) decreased to zero when the test temperature reached -195 °C (-320 °F). The variation in strain rate had little effect on the uncharged specimens. For the charged specimens (Fig. 40b), a marked reduction in tensile ductility is evident, with decreasing strain rate in the center of the test temperature range producing two intersecting surfaces (coded a and d in Fig. 40b). Surface, in the lower-temperature test region, shows that ductility decreases with increasing temperature and decreasing strain rate. Surface d, in the higher-temperature test region, shows that ductility decreases with decreasing temperature and decreasing strain rate. As the strain rate increases, the temperature for lowest ductility (the intersection of surfaces a and d) increases from about -40 to 50 °C (-40 to 120 °F).

Fig. 40 Tensile ductility of AISI/SAE 1020 carbon steel as a function of strain rate and test temperature for (a) spheroidize-annealed specimens and (b) cathodically charged specimens. Curve *i* bounds the range of strain rates and temperatures where embrittlement was observed. Source: Ref 255

Figure 41 shows the test results for charged specimens as a function of charging time at lowest strain rate, 0.05 min⁻¹. The graph shows the loss in fracture ductility with increased charging time and the increase in hydrogen content. The loss in ductility becomes relatively constant after about 30 min charging time.

Fig. 41 Fracture strain and hydrogen content of AISI/SAE 1020 steel as a function of charging time for tensile tests conducted at room temperature, with a strain rate of 0.05 min^{-1} . Source: Ref 255

A correlation has also been demonstrated between total hydrogen content and tensile reduction in area (Ref 256). Test specimens were machined from the center, midpoint, and edge of a $127 \times 127 \text{ mm}$ ($5 \times 5 \text{ in.}$) square billet of AISI 1010 carbon steel known to have a rather high hydrogen content. Reduction in area results were 13.4, 23.0, and 33.1% with corresponding hydrogen contents of 5.7, 5.2, and 3 ppm. A midpoint specimen aged at 175°C (350°F) for 15 h had a 64% reduction in area and contained 1.4 ppm hydrogen. Fisheyes were observed on the nonaged specimen fractures but not on those that were aged. Eight months later, additional tests were made with better percentage reduction in area values and less of a ductility gradient across the billet. Figure 42 shows the results from these two test periods. The values on the graph indicated by the solid dots were from similar tests made on a $127 \times 127 \text{ mm}$ ($5 \times 5 \text{ in.}$) billet from another heat of the same grade.

Fig. 42 Relationship between hydrogen content and tensile reduction in area for two heats of AISI 1010 steel. Source: Ref 256

Hydrogen-induced fractures are not always intergranular. In high-strength steels, cracking is often intergranular, but transgranular cleavage is also observed. For ductile low-strength steels, the fracture mode is ductile with changes in the dimple size. Prior temper embrittlement of high-strength alloy steels enhances hydrogen stress cracking (Ref 257, 258, 259, 260, 261). The threshold stress intensity for crack growth is lowered, and intergranular fractures occur. The influence of temper embrittlement on hydrogen stress cracking is particularly pronounced as the yield strength is decreased. Very low impurity content steels do show high threshold stress intensity values and freedom from intergranular fracture (Ref 258).

Hydrogen-assisted ductile fractures have been reported for a variety of steels, chiefly spheroidized carbon steels and austenitic stainless steels (Ref 262, 263, 264, 265, 266). The fractures exhibit ductile dimples (microvoid coalescence), and the dimple sizes in charged specimens have been reported to be either smaller or larger than those in uncharged specimens. The change in dimple size can be correlated with the loss in tensile reduction of area (Ref 262).

Austenitic Stainless Steels. For many years, it was believed that only bcc metals were susceptible to hydrogen embrittlement. However, it has since been shown that austenitic stainless steels, and several other fcc metals and alloys, can become embrittled by hydrogen, and their behavior is similar in nature to the bcc metals (Ref 242, 267). A number of studies have focused on hydrogen-embrittled AISI 304 or 304L. These studies have demonstrated that hydrogen charging partially transforms the austenite to α' (bcc) and ϵ (hexagonal close-packed) martensites (Ref 268). These phases can also be formed in 304 or 304L, and in other low-stability austenitic stainless steels, by cold working (uncharged) specimens at low temperatures. Tests of more stable austenitic grades, such as AISI 310, have produced conflicting results. While some studies showed no embrittlement (Ref 269), others detected embrittlement. The unstable 304 alloy exhibits transgranular cleavage fractures, and the stable 310 alloy exhibits ductile fractures, when tested in hydrogen gas environmental cells (Ref 270).

Tool Steels. Fracture mechanics approaches have also been used to study crack nucleation and growth in hydrogen-containing environments. Studies have demonstrated that high-strength steels are embrittled by exposure to hydrogen gas even at, or below, atmospheric pressure (Ref 271). For example, a study was conducted on the effect of hydrogen gas at atmospheric pressure on subcritical crack growth using AISI H11 tool steel (Ref 272). Although argon, helium, and nitrogen are inert environments, if they are humidified, subcritical crack growth occurs. The study also demonstrated that the addition of oxygen to the environment, even in amounts as low as 0.7% by volume, would terminate crack growth. The removal of the oxygen would restart crack growth. Oxygen dissolved in water, however, had no influence on the crack growth rate. Figure 43 shows results for H11, quenched and tempered to a yield strength of 1585 MPa (230 ksi), using a precracked specimen under load in various environments. For the first 5 min, the crack grew slowly in humidified argon. Then, an equal volume of oxygen was added to the environment, and cracking stopped for the next 5 min. Next, this environment was removed and replaced by pure hydrogen, and crack growth was very rapid. After about 1 min, the pure hydrogen was replaced by humidified argon, and the crack growth rate decreased. Again, an equal volume of oxygen was added to the humidified argon, and crack growth ceased. This atmosphere was removed and replaced by water, and the crack again began to grow at a constant rate.

Fig. 43 Influence of oxygen on crack growth in AISI H11 tool steel quenched and tempered to a yield strength of 1585 MPa (230 ksi). Source: Ref 272

Maraging Steels. The influence of hydrogen of slow crack growth in maraging steels has been examined by several researches. One study determined the critical stress intensity for slow crack growth in hydrogen-precharged 18% Ni maraging steels and for 300M alloy steel (Ref 273). The maraging steel was tested at three yield strength levels: 1750, 1880, and 2020 MPa (254, 273, and 293 ksi); the 300M was tested at a yield strength of 1705 MPa (247 ksi). Specimens were charged with different levels of hydrogen, and the critical stress intensity for slow crack growth was determined (Fig. 44). Each of the four steels contained about 0.5 ppm H prior to charging, and the K_{Ic} values for the noncharged specimens are plotted at this value (dashed line). The data points for the charged specimens are the critical stress intensities where slow crack growth began. Note that the lowest-strength maraging specimens, with the highest K_{Ic} , had the highest critical stress intensities after charging. The critical stress intensities for the two higher-strength maraging steels were the same after charging to the same hydrogen levels despite their substantial differences in K_{Ic} . The 300M alloy, with the lowest yield strength (1705 MPa, or 245 ksi) and a K_{Ic} only slightly greater than the highest yield strength (2020 MPa, or 292 ksi) maraging grade, had much lower critical stress intensities and was more susceptible to hydrogen embrittlement.

Fig. 44 Influence of hydrogen content on the critical stress at and below which cracks do not grow. Alloys A, B, and C are three different 18% Ni maraging steels at increasing levels of yield strength (1740, 1870, and 2020 MPa, or 252, 271, and 293 ksi); alloy D is 300M alloy steel at 1705 MPa (247 ksi). Source: Ref 273

Similar tests were performed using 18% Ni maraging steel at two different yield strengths: 1650 and 1915 MPa (239 and 278 ksi) in high-purity hydrogen at pressures from 11.5 to 133.3 kPa (86 to 1000 torr) (Ref 274). The crack growth rate as a function of the crack tip stress intensity, K , was determined for each steel as a function of temperature and hydrogen pressure. This information was used to determine the critical or threshold stress intensity, K_{th} , at which crack growth began. At K values above K_{th} , the crack growth increased (stage I). At intermediate K values, crack growth became relatively constant over a range of K values (stage II). At higher K values, crack growth became rapid (stage III) up to specimen failure. Figure 45 shows the data for the 1650 MPa (239 ksi) yield strength 18Ni(250) maraging steel tested in hydrogen at 133.3 kPa (1000 torr) for stage I and II crack growth. Over the temperature range of -60 to 23 °C (-75 to 73 °F), the apparent threshold stress intensity, K_{th} , varies only slightly from about 11 to 16.5 MPa \sqrt{m} (10 to 15 ksi \sqrt{in}). No detectable crack growth was observed at 50 or 80 °C (120 or 175 °F) for K levels up to 79 and 92 MPa \sqrt{m} (72 and 84 ksi \sqrt{in}), respectively. In the stage II regime, where the crack growth rate (da/dt) was constant, the highest crack growth rate occurred at 23 °C (73 °F). Figure 46 shows crack growth data for stage II crack growth as a function of test temperature and hydrogen pressure. The upper curve shows data for hydrogen at 133.3 kPa (1000 torr). At low temperatures, the crack growth rate increased with increasing temperature (region A) until a temperature range was reached where the crack growth did not vary much with temperature (region B), and the maximum crack growth rate was obtained. With further increases in temperature, the crack growth rates decrease rapidly (region C). Lowering the hydrogen pressure shifts the curves to lower crack growth rates, and the temperature for the maximum crack growth rate appears to decrease slightly.

Fig. 45 Crack growth rates of 18Ni(250) maraging steel (1648 MPa, or 239 ksi, yield strength) in hydrogen at 133 kPa (1000 torr) as a function of test temperature and stress intensity range. Source: Ref 274

Fig. 46 Effect of test temperature on stage II crack growth rates for 18Ni(250) maraging steel in gaseous hydrogen at different pressures (133, 57, 28, and 11.5 kPa, or 1000, 430, 210, and 86 torr). Source: Ref 274

Another study also tested 18% Ni maraging steels at two different yield strengths (18Ni(200) at 1270 MPa, or 184 ksi, and 18Ni(250) at 1650 MPa, or 239 ksi) in low-pressure hydrogen (Ref 275). Figure 47 shows a plot of the apparent threshold stress intensity level for the onset of slow crack growth, K_{th} , for these two grades in hydrogen at 133 kPa (1000 torr) and over the temperature range of -60 to 60 °C (-75 to 140 °F). The K_{th} is quite low at low temperatures (stage II) and increases slowly with increasing temperature until a temperature is obtained at which K_{th} increases rapidly and K_{Ic} is reached. The lower-strength steel has higher, K_{th} values at low temperatures, and its critical temperature (where K_{th} increases rapidly) occurs at a much lower temperature than it does for the higher-strength grade.

Fig. 47 Effect of test temperature on the apparent threshold stress intensity factor for two maraging steels tested in gaseous hydrogen at 133 kPa (1000 torr). Source: Ref 275

Line Pipe Steels. Blisters form in steels when atomic hydrogen enters the steel from the surrounding environment. The hydrogen diffuses through the steel to an internal defect or inclusion, where it builds up as molecular hydrogen. This process produces high pressure, which causes a blister to form. The blister will grow as more hydrogen diffuses to it, deforming the surrounding metal until it ruptures. Blister formation is observed in environments containing hydrogen sulfide or where hydrogen is electrolytically charged. Blister formation is common in the more ductile steels, such as sour gas transmission line pipe steels (Ref 276, 277, 278).

Hydrogen-induced blistering of line pipe steels results from contact with wet environments containing H_2S . Hydrogen diffuses to inclusions and precipitates at the inclusion/matrix interface. A blister-crack array forms; cracking of the metal around the blisters is caused by the molecular hydrogen pressure and applied or residual stresses. These crack arrays are internal, rather than at the surface. Elongated manganese sulfides are the most common nucleation sites, but cracking can also occur at manganese silicates and at large complex carbonitrides.

It is well known that high sulfur contents are highly detrimental for sour gas applications. High-quality line pipe steels require very careful processing, which involves desulfurization to very low levels, sulfide shape control, controlled rolling, grain refinement, and segregation control.

Formation of Flakes in Steels. Flaking or hairline cracking in steels, particularly in forgings, heavy-section alloy plate steels, and railroad rails, has been an ongoing problem since the beginning of steelmaking (Ref 279 280 281 282 283 284 285 286 287 288 289). Flakes are caused by an excessive hydrogen content, that is, hydrogen above some safe level or threshold level. This safe level varies somewhat with steel composition, section thickness, cooling rate, inclusion

content, and segregation and is generally in the range of 1 to 2 ppm. Some steel compositions, particularly low-carbon steels, appear to be rather free of flaking problems.

The solubility of hydrogen in liquid steel decreases substantially when it solidifies (to about 7 ppm in δ iron). With continued cooling, it decreases to about 5 ppm and then at the γ to α transformation it abruptly drops to about 2.5 ppm. With continued cooling, it decreases to less than 1 ppm at room temperature. Some of the hydrogen present in excess of the solubility limit at room temperature can be accommodated at microstructural traps, such as sulfide inclusions, and rendered harmless. However, if the hydrogen content is too high, cracking will occur after a certain delay time, usually less than 2 weeks, unless the steel is reheated to a temperature where it can safely diffuse out of the steel. In the years prior to the development of vacuum degassing (even today for some steels, such as rails), wrought or forged products susceptible to flaking were held at temperatures between about 500 and 650 °C (930 and 1200 °F) for a time that depended on the product thickness; this was done before the products were cooled to ambient temperature, and it allowed the hydrogen content to decrease to a safe level. With the drive to produce steels with lower sulfur contents, rail producers have discovered that these safe controlled-cooling practices have had to be extended for further hydrogen removal because of the decrease in hydrogen traps available. Similar flaking problems have occurred in low-sulfur plate steels that were free of such problems at the former higher-sulfur levels.

An interesting study was done of flake formation in plain carbon steels (AISI 1045 and 1080) and in nickel-molybdenum-vanadium and nickel-chromium-molybdenum-vanadium forging steels melted and teemed to produce a range of hydrogen contents (Ref 287). Five ingots of each grade were produced and rolled to 305 mm (12 in.) square blooms, and each was hot sheared to produce four 610 mm (24 in.) long sections. These sections were cooled at different rates and by different methods (water quench, air cool, hood cool, and slag cool). After a 2-week incubation period, to permit flaking to occur, transverse disks were cut from each block, macroetched, and examined. The total number of flakes were counted, except for disks that were quench cracked. Hydrogen analyses of the blocks were made immediately after cooling to a safe handling temperature.

The study showed that the number of flakes increased with the cooling rate (Ref 287). The flakes were generally located in a circumferential pattern between the surface and the center of the block and as the cooling rate decreased, they were closer to the center. In general, as the number of flakes decreased, their size increased.

Figure 48 shows data for the relationship between the number of flakes on the etch disks as a function of the cooling rate and hydrogen content for each grade. Quench cracking, which occurred in some of the water quenched blocks, made the analysis more difficult by requiring the use of an estimated value of the number of flakes (dashed lines). In general, water quenching produced about twice as many flakes as did air cooling. The 1045 and nickel-chromium-molybdenum-vanadium steels had low susceptibilities to flaking at hydrogen levels of 4 and 3.8 ppm. The 1080 and nickel-molybdenum-vanadium steels were much more susceptible at hydrogen levels of 4.0 and 3.5 ppm. Based on the number of flakes, a relative susceptibility of 1 was assigned for 1045 and nickel-chromium-molybdenum-vanadium, and values of 8 and 75 were assigned for air-cooled blocks of 1080 and nickel-molybdenum-vanadium. The figure also shows the influence of hydrogen content on the nickel-molybdenum-vanadium steel blocks with hydrogen contents of 3.5 and 2.0 ppm. Reducing the hydrogen content of the steel from 3.5 to 2.0 reduced its susceptibility to a level similar to that of the 1045 and nickel-chromium-molybdenum-vanadium steels (indicated by the lower curve for nickel-molybdenum-vanadium). For the 1080 steel, the flaking index was 8 at 4.0 ppm; at 3.7 ppm it flaked only when water quenched, and at 2.2 ppm it did not flake even when water quenched. These results for nickel-molybdenum-vanadium and 1080 as a function of hydrogen content and cooling rate are better shown in Fig. 49, which clearly demonstrates the presence of a critical threshold level of hydrogen in these flake-sensitive steels. The threshold levels were approximately 3.5 ppm for 1045 and nickel-chromium-molybdenum-vanadium, 3.3 ppm for 1080, and 1.6 ppm for nickel-molybdenum-vanadium. The high susceptibility of the nickel-molybdenum-vanadium steel was attributed to the high transformation stresses associated with the formation of martensite from enriched austenite; the high susceptibility of 1080 was attributed to its low fracture toughness.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Metal-Induced Embrittlement

The term metal-induced embrittlement (MIE) applies to cases in which contact with a liquid metal embrittles a solid metal (liquid metal embrittlement, LME) or in which contact with a solid metal somewhat below its melting point (solid metal embrittlement, SME) embrittles a solid metal. Only recently has a distinction been made between these two forms of MIE. Historically, LME was the term used to describe all MIE problems.

Liquid Metal Embrittlement

Liquid metal embrittlement is a phenomenon in which the ductility or fracture stress of a solid metal is reduced by surface contact with a liquid metal. The first recorded recognition of this problem was made in 1914 when the embrittlement of β brass by mercury was observed (Ref 290). Since then, LME has been identified as the cause of numerous failures, and numerous reviews of LME have been published (Ref 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301).

There are at least four distinct forms of liquid metal embrittlement (Ref 292):

- *Type 1*: Instantaneous fracture of a metal under an applied or residual tensile stress when in contact with certain liquid metals. This is the most common type of LME
- *Type 2*: Delayed failure of a metal when in contact with a specific liquid metal after a certain time interval at a static load below the ultimate tensile stress of the metal. This form involves grain-boundary penetration by the liquid metal and is less common than type 1
- *Type 3*: Grain-boundary penetration of a solid metal by a specific liquid metal, which causes the solid metal to eventually disintegrate. Stress does not appear to be a prerequisite for this type of LME in all observed cases
- *Type 4*: High-temperature corrosion of a solid metal by a liquid metal, causing embrittlement, an entirely different problem from types 1 to 3

In some respects, LME is similar to stress-corrosion cracking (SCC), which always requires a measurable incubation period before fracture occurs. Stress-corrosion cracking is more similar to type 2 LME than to the other types. This review will concentrate on the influence of MIE on the mechanical properties of ferrous alloys.

A number of observations have been made of interactions between liquid metal and solid metal. These observations can be classified as (Ref 291):

- No observed interaction
- Dissolution of the solid metal into the liquid metal. Diffusion of the liquid metal into the solid metal
- Formation of intermetallic compounds at the liquid/solid interface
- Intergranular penetration of the liquid metal into the solid metal without the presence of applied or residual stress
- Brittle premature failure of the solid metal caused by intergranular penetration of the liquid metal into the solid metal under the influence of applied or residual tensile stress. Failure occurs after a finite incubation period
- Brittle instantaneous failure of a stressed metal when wetted by a specific liquid metal. Grain boundary penetration is not necessarily observed.

The last three observed interactions are the prime forms of liquid metal embrittlement. Most studies of LME have been concerned with the form that causes instantaneous failure of the solid metal, the most common form. This type of LME has been referred to as adsorption-induced embrittlement. Liquid metal embrittlement is often considered a special type of brittle fracture, and fracture mechanics approaches have been applied to its analysis.

Many different metals and alloys besides ferrous alloys can fail because of LME. Only specific liquid metals are known to cause LME of each specific metal or alloy. Indeed, this is one of the more perplexing aspects of LME, and some investigators refer to it as specificity (Ref 302). However, studies have generally used tests involving a limited number of conditions, for example, a single temperature, applied stress, grain size, and so on, and until a much wider range of variables has been tested, the validity of this concept cannot be proved. Also, many LME tests have been of the go/no go type rather than quantitative measurements of the degree of embrittlement.

Certain conditions are recognized as being required for, but not necessarily sufficient to cause, embrittlement. These conditions include (Ref 291):

- Adequate wetting of the solid-metal substrate by the liquid metal
- An applied or residual stress present in the solid metal
- A barrier to plastic flow existing at some point in the solid metal that is in contact with the liquid metal

Of course, for failure to occur, the liquid metal must be of the correct composition to cause LME of the solid metal.

If the solid metal is not notch sensitive, as in the case of fcc metals, the crack will propagate only when the liquid metal feeds the crack. However, for a notch-sensitive metal, such as bcc metals like iron, the nucleated crack may become unstable and propagate ahead of the liquid metal. Crack propagation can be extremely rapid; rates between 500 and 5000 mm/s (20 and 200 in./s) have been recorded (Ref 293). In most cases, crack paths are intergranular, but transgranular cracking has been observed, and a few cases of ductile fracture have even been reported. Factors that influence the fracture stress and ductility of metals subject to LME include:

- Composition of the solid and liquid metals
- Temperature
- Strain rate
- Grain size
- Thermal-mechanical history of the solid metal

Some of the earliest studies of LME did not recognize the important role of stress in LME (Ref 303). Some early studies, however, did demonstrate the significance of stress in producing LME (Ref 304, 305, 306). Tensile stresses, either applied or residual, are required, while the solid metal is wet by the liquid metal. Again, a certain critical stress

(threshold) can be identified above which cracking occurs and below which it does not. Subsequent studies focused on the identification of specific liquid-solid metal couples that undergo LME.

Studies of specific LME couples have empirically identified certain trends that are usually, but not always, obeyed. For example, most LME couples have very little mutual solid solubility and exist as immiscible liquids in the liquid state. Solid metals that are highly soluble in the liquid metal and solid-liquid metal combinations that form intermetallic compounds are usually immune to LME. Such studies have demonstrated that good wetting of the substrate is required. It is interesting that the factors that promote the lowest interfacial energy and therefore the best wetting are high mutual solid solubility and intermetallic compound formation, both of which promote low susceptibility to LME. A number of studies have examined the effect of adding various solute elements to particular liquid metals, but no clear trends have been identified.

Several researchers have attempted to correlate the occurrence and severity of LME for particular couples with the electronegativities of the metals. For some couples, maximum embrittlement arises when the solid and liquid metals have similar electronegativities. As the difference in electronegativity increases, the degree of embrittlement decreases. While many examples support this relationship, exceptions also exist (Ref 294).

The presence of notches (stress concentrators) increases the severity of LME, and this has prompted the use of fracture mechanics concepts in the study of LME. As stress raisers are well known to be a detrimental influence in brittle fracture, their effect on LME is understandable.

Reference 301 reports the results of a very extensive literature survey concerning the nature of occurrence of LME. The following liquid metals have been reported to cause LME of ferrous alloys: aluminum (minor LME for pure iron, no LME for a 0.2% C steel), antimony, bismuth (both positive and negative results have been reported), cadmium, copper, gallium (both positive and negative results have been reported), indium, lead, lithium, mercury, sodium, tellurium, tin, and zinc. Solders, bearing metals, and brazing alloys have also been shown to produce LME in certain tested ferrous alloys. As might be expected, for each of the above-mentioned liquid metals only a limited range of solid ferrous alloys has been evaluated. Liquid metals that have not been found to cause LME of ferrous alloys include cesium, rubidium, selenium, silver (although silver-containing brazing alloys do cause LME), and thallium. Reference 301 contains source data for these observations and should be consulted for further information.

The effect of test temperature, T , is complex and is not predictable. Generally, temperature increases above the melting point of the embrittling liquid decrease the degree of embrittlement. Maximum embrittlement often occurs near the melting point of the liquid, T_m . In many couples, embrittlement occurs below the melting point of the liquid. For example, the embrittlement of AISI 4140 alloy steel starts at temperatures below the melting point for cadmium ($T/T_m = 0.75$) and for lead and tin ($T/T_m = 0.85$) (Ref 307). This phenomenon is called solid metal embrittlement or solid metal induced embrittlement. In other cases, the liquid temperature must be above T_m , as for the embrittlement of austenitic stainless steel by zinc. It has been reported that the zinc embrittlement of austenitic stainless steels has not been observed below 750 °C (1380 °F), which is well above the melting point of zinc (419 °C, or 786 °F) (Ref 308).

Liquid metal embrittlement reduces tensile ductility and stress at fracture if the failure occurs at a stress below the usual yield strength of the metal. The time to fracture is usually directly related to the level of the applied stress. At some high level of applied stress, fracture can occur immediately after the specimen is wetted by the liquid metal. As the level of applied stress is reduced, the time to failure increases. This is shown in Fig. 50, which shows test results for AISI 4130 steel at 44 HRC immersed in molten lithium at 200 °C (390 °F). As the applied stress decreased from 310 to 138 MPa (45 to 20 ksi), the time to failure increased from about 1 s to 1 to 200 min.

Fig. 50 Time to fracture as a function of applied load for AISI 4130 alloy steel specimens (at 44 HRC) wetted with molten lithium at 200 °C (390 °F). Source: Ref 291

The strength of the material also influences LME results. Figure 51 demonstrates this by showing the normal tensile strength of AISI 4130 alloy steel quenched and tempered to hardnesses from 20 to 55 HRC and the corresponding fracture strength of specimens wet with liquid lithium at 205 °C (400 °F). At tensile strengths above 1035 MPa (150 ksi), catastrophic embrittlement occurs (Ref 291). Tensile ductility, however, was reduced at all of the strength levels.

Fig. 51 Plot of hardness versus tensile strength for AISI 4130 alloy steel with and without wetting by molten lithium at 205 °C (400 °F). Source: Ref 291

While the majority of LME studies have been conducted using tensile specimens, some work has been done using fatigue loading conditions. Figure 52 shows axial load fatigue tests of AISI 4340 with a tensile strength of 1310 MPa (190 ksi) tested at a stress ratio of 0.75 with or without a coating with liquid mercury (Ref 291). As the maximum applied stress decreased, the coated specimens exhibited a proportionally lower fatigue life than did the uncoated specimens.

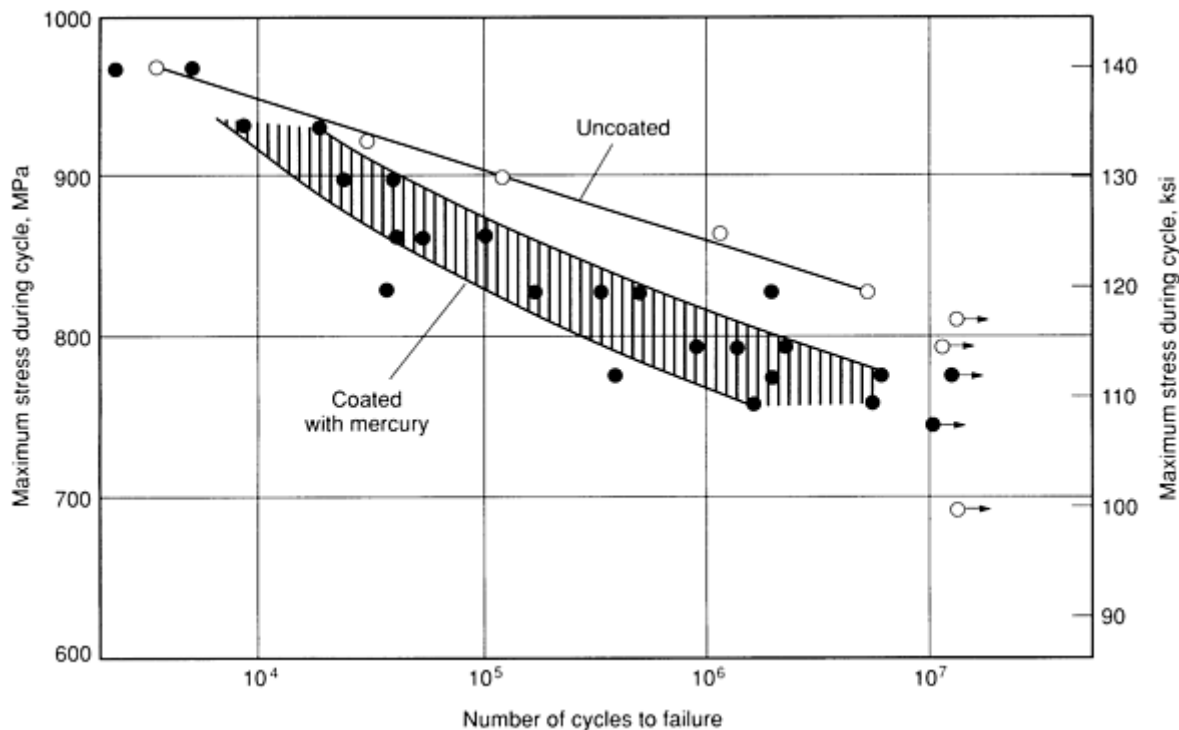

Fig. 52 Fatigue life under axial loading for AISI 4340 alloy steel (1310 MPa, or 190 ksi, tensile strength) wetted with mercury. Source: Ref 291

Fatigue crack growth rate measurements were performed using liquid lithium and AISI 304L stainless steel at temperatures ranging from 473 to 973 K (200 to 700 °C) (Ref 309). Figure 53 shows the crack growth data from these tests as a function of temperature for 304L specimens in argon and in liquid lithium using two different test frequencies and a stress intensity range of $14 \text{ MPa } \sqrt{m}$ ($12.7 \text{ ksi } \sqrt{in}$). The crack growth rates in lithium were much greater than those in argon at all temperatures and load frequencies. In lithium, the crack growth rate decreased as the temperature increased from 473 to about 700 K (200 to 700 °C) and then increased strongly with further increases in temperature.

Fig. 53 Influence of test temperature and environment (argon versus molten lithium) on the crack growth rate using two different loading frequencies and a stress intensity factor range of $14 \text{ MPa } \sqrt{m}$ ($12.7 \text{ ksi } \sqrt{in}$) for AISI 304L stainless steel. Source: Ref 309

Crack propagation in argon was transgranular for all test conditions. At 573 K (300 °C) in lithium, a mixture of transgranular cleavage and intergranular fracture was observed that varied with load frequency and stress intensity range (Fig. 54). The percentage of intergranular fracture increased with decreasing stress intensity range and increasing frequency. The influence of load frequency at 573 and 873 K (300 and 600 °C) is shown in Fig. 55. The effect of frequency on the amount of intergranular fracture at 873 K (600 °C) is opposite to that at 573 K (300 °C). This difference was also accompanied by a difference in the appearance of the intergranular facets; at 873 K (600 °C), the facets were rounded, with numerous dimples; at 573 K (300 °C), the facets were sharp, and occasional tears and slip bands were observed.

Fig. 54 Influence of loading frequency and stress intensity factor range on the percentage of intergranular fracture for AISI 304L in molten lithium at 573 K (300 °C). Source: Ref 309

Fig. 55 Influence of loading frequency and temperature of lithium on the percentage of intergranular fracture for AISI 304L. Stress intensity factor range, ΔK , was $\text{MPa}\sqrt{\text{m}}$ ($12.7\text{ ksi}\sqrt{\text{in.}}$). Source: Ref 309

The liquid metal embrittlement failures of steels caused by molten copper and copper-base alloys are common, and numerous studies have been made. Such failures are characterized by grain-boundary penetration of liquid copper, which can be quite rapid. One of the earliest studies of LME of steel, in this case by molten brass, was made in 1927 (Ref 310). An evaluation of the influence of various liquid metals on plain carbon steel, silicon steel, and chromium steel found that these steels were embrittled at 1000 to 1200 °C (1830 to 2190 °F) by liquid tin, zinc, antimony, copper, 5% tin-bronze, and 10% zinc-brass; liquid bismuth, cadmium, lead, and silver caused little or no embrittlement (Ref 311).

A series of studies of LME of iron by liquid copper was done using tests performed under nonoxidizing conditions with notched tensile creep specimens at 1100 to 1130 °C (2010 to 2065 °F) and stresses of 8.3 and 11.0 MPa (1.2 and 1.6 ksi) (Ref 312, 313, 314, 315). Liquid copper significantly altered the creep behavior of pure iron, causing premature failure. Embrittlement was of the delayed type controlled by grain-boundary copper penetration. The depth of surface cracking was controlled by the depth of copper penetration. Dihedral-angle measurements for liquid copper in the steel grain boundaries revealed that 34° was the most frequent angle for exposure at 1100 or 1130 °C (2010 or 2065 °F).

Liquid metal embrittlement of steels by copper has also been encountered during welding and joining processes. An examination of copper weldment deposition on ferritic and austenitic stainless steels in duplex ferrite-austenite grades found that stable ferrite reduced the penetration of copper; if ferrite was in excess of 30%, penetration did not occur. Also, copper deposited on fully ferritic grades did not cause cracking, but it did in austenitic grades. Wetting by molten copper was also examined. A contact (dihedral) angle of 92 to 100° was observed for ferritic grades (no wetting of the grain boundaries) and 22 to 28° for the austenitic grades (wetting) at 1100 °C (2010 °F) (Ref 316).

A series of studies has examined LME of steels by copper during welding (Ref 317, 318, 319, 320). A study of HY-80 steel welded with or without copper-nickel filler metal found infiltration of the grain boundaries by the copper-nickel deposit under an applied strain field in the heat-affected zone while the steel was austenitic. Heat affected zone areas that remained ferritic were not penetrated (Ref 317). In another study involving copper deposition by a gas metal arc, alloy steels such as AISI 4340, 4140, and 304 were found to be extremely sensitive to copper penetration. In comparison, penetration depths for AISI 1340, 1050, Armco iron, and carburized Armco iron were only about one-third that of the alloy steels. A ferritic stainless steel, AISI 430, was almost completely immune to copper LME. The study concluded that, when stresses were absent, the ease of penetration by molten copper was a function of the alloy content of the steel. Grain-boundary copper penetration occurred under an applied stress, forming partially filled or open cracks in the steel. Steels that remained ferritic at the melting point of copper were not penetrated (Ref 318).

As reviewed earlier in the section "Aluminum Nitride Embrittlement," residual copper can detrimentally influence the hot workability of steel by internal LME. Reference 321 summarizes work on the influence of copper on the hot workability and scaling characteristics of steels. Elements such as tin, arsenic, and antimony dissolved in the steel increase the sensitivity of surface cracking that is due to copper.

Perhaps the most common LME failure is the fracture of railroad axles caused by copper penetration from overheaded friction bearings. These failures are relatively common, even today, and have been observed ever since the development of railroads. A friction bearing consists of a bronze shell lined with babbitt metal bonded to the inner surface. The bearing is lubricated through an opening in the shell, which is packed with cotton waste. Oil from a reservoir is carried to the bearing through the cotton waste by a wicklike mechanism. In 1914, a study presented results for a Krupp axle that failed in service (Ref 322). The surface of the axle had been exposed to very high temperatures, as evidenced by the microstructural changes, and cracking was present. The heated region was the part of the axle within the support bearing. Bronze bearing metal was observed to be associated with the cracks and grain-boundary penetration. Such failures still occur and have recently been reviewed (Ref 323).

Solid Metal Embrittlement

Solid metal embrittlement occurs when the temperature is somewhat below the melting point of the embrittling metal (Ref 297, 300, 307, 324, 326). Its characteristics, except for this distinction, are quite similar to that of LME. Crack propagation rates for SME, however, are much slower than for LME, and multiple cracking is often observed in SME, but not in LME.

Iron-Base Alloys. Solid metal embrittlement of iron-base alloys can be caused by a number of low melting point metals. Solid metal embrittlement of steels by cadmium (Ref 307, 326, 327) was studied in depth as a result of the fracture of cadmium-plated nuts (Ref 327). The failures occurred in the temperature range of 200 to 300 °C (390 to 570 °F), which is well below the melting point of cadmium (321 °C, or 610 °F). Crack propagation rates increase with temperature (below the melting point, T_m), and a threshold stress level is required for cracking (Ref 328).

Leaded Alloy Steels. Solid metal embrittlement of leaded alloy steels, that is, internal rather than external embrittlement, has been studied extensively (329, 330, 331, 332, 333). Reference 329 contains the first discussion of the differences between liquid metal and solid metal embrittlement. Short-time high-temperature tensile specimens of AISI 4140 and 41L40 (leaded) were tested between room temperature and approximately 480 °C (900 °F). The melting point of lead is 327 °C (621 °F). Tensile test results for the leaded and nonleaded steels were compared. Figure 56 shows the

ratio of the percentage reduction in area of the leaded steel to the unleaded steel for tensile strength levels from 825 to 1515 MPa (120 to 220 ksi) and temperatures from ambient to approximately 480 °C (900 °F). The ductility of the leaded steels was substantially reduced at temperatures well below the melting point of lead. The loss in ductility increased with tensile strength and was greatest at temperatures just above the melting point of lead. By 480 °C (900 °F), most of the ductility has been recovered. Similar tests of leaded and nonleaded Charpy V-notch impact specimens revealed that embrittlement effects were apparent beginning at about 28 °C (50 °F) below the melting point, suggesting a sensitivity to strain rate. Also, when comparing the ultimate tensile strength for leaded and non-leaded specimens as a function of hardness at the maximum embrittlement temperature (370 °C, or 700 °F), results were quite similar to those shown in Ref 291 for AISI 4130 in liquid lithium at 205 °C (400 °F) (Fig. 51). Catastrophic failure occurred for leaded steels at tensile strengths above 965 to 1140 MPa (140 to 165 ksi).

Fig. 56 Relative decrease in the percent reduction of area for leaded versus nonleaded tensile specimens of AISI 4145 alloy steel as a function of test temperature and ultimate tensile strength (825 to 1655 MPa, or 120 to 240 ksi). Source: Ref 329

A fractographic examination was done of these test fractures (Ref 330). Five types of fractures were observed that related to the test temperature. Tensile specimens broken at temperatures up to 205 °C (400 °F) exhibited the classic cup-and-cone fracture and failed by microvoid coalescence (ductile). Specimens tested between 205 and 315 °C (400 and 600 °F) exhibited small shear lips and a mixture of intergranular fracture regions within a transgranular fracture. This was the range where embrittlement (SME only) began and became progressively worse. Tensiles broken between 315 and 345 °C (600 and 650 °F) showed severe embrittlement and numerous coarse facets (called "fisheyes" by the authors of the study). Fracture was a mixture of transgranular and intergranular modes. Tensile specimens broken between 345 and 480 °C (650 and 900 °F), covering the region of maximum embrittlement to recovery, exhibited large shear lips and a large faceted origin. The fractures were completely intergranular and were moving away from the origin toward the opposite shear lip. Inclusions were always observed to be associated with the intergranular facets. Above 480 °C (900 °F), the ductility was recovered, and there was a return to a cup-and-cone fracture.

Leaded Carbon and Alloy Steels. An evaluation of a variety of leaded carbon and alloy steels found that all were subject to SME and LME (Ref 331). Embrittlement began at about the same temperature and was most severe in the same temperature range, 315 to 370 °C (600 to 700 °F), but the recovery of ductility of higher temperatures varied somewhat, from about 400 to 480 °C (750 to 900 °F). It was thought that the composition of the lead could be affecting this brittle-to-ductile transition temperature, T_r .

Subsequent work compared externally applied liquid lead and lead alloys to the previous internal lead work (Ref 332, 333). Nonleaded AISI 4145 tensile specimens at a tensile strength of 1380 MPA (200 ksi) were externally wetted with high-purity lead and lead-antimony alloys. For the high-purity lead, embrittlement began at lower temperatures, and the recovery of embrittlement occurred at a lower temperature (370 °C, or 700 °F), than for the internally embrittled leaded steels. Additions of up to 2% Sb were made to the pure lead, and similar tests were run that showed that the onset of embrittlement, the temperature range for severe embrittlement, and the temperature for the recovery of ductility were all affected by the addition of antimony (Fig. 57) (Ref 332, 333). As the antimony content increased to 0.3%, T_r gradually increased. However, for the 1 and 2% Sb specimens, little or no evidence for recovery was obtained up to 480 °C (900 °F). Similar work was done for lead containing up to 9% Sn (Ref 333). Results were similar for tin except that on a weight percent basis, it enhanced lead embrittlement less than antimony additions did.

Fig. 57 Effect of adding antimony to lead on (a) the tensile reduction in area and (b) fracture strength as a function of test temperature for externally embrittled AISI 4145 steel heat treated to a yield strength of 1380 MPa (200 ksi). Source: Ref 333

Combined SME and LME has been demonstrated for AISI 4140 alloy steel (1380 MPa, or 200 ksi, tensile strength) in contact with pure zinc, lead, cadmium, tin, and indium over the temperature range from ambient to the melting point of the pure, low melting point alloy (Ref 307). Figure 58 shows test results for 4140 in contact with these metals. All of the data have been normalized for ease of comparison. Temperature is expressed in homologous fashion (that is, by the ratio of the test temperature used to the melting point of the embrittler):

$$T_H = \frac{T}{T_m} \quad (\text{Eq 4})$$

where T_H is the homologous temperature. The true fracture strength (TFS) ratio is the ratio of the true fracture stress of the embrittlement couple to the true fracture stress of uncoated 4140 at the same temperature; the reduction in area (RA) ratio is defined in the same way, based on the percentage reduction in area values. As the melting point of the embrittler is approached, the TFS ratio and RA ratio decrease. For temperatures at the melting point of the embrittler, RA ratios vary from 0 to approximately 0.2, indicating severe embrittlement. All of the elements in this test were potent embrittlors when the test temperature was increased to about 75% of the melting temperature.

Fig. 58 Normalized true fracture strength ratio and reduction of area ratio as a function of the homologous temperature ($T_H = T/T_m$) for heat-treated AISI 4140 alloy steel in external contact with solid lead, cadmium, zinc, tin, and indium. Source: Ref 307

Times to failure are reported in Ref 326 for AISI 4140 (1380 MPa, or 200 ksi, tensile strength) in contact with solid zinc, lead, cadmium, tin, and indium at temperatures below the melting points of the embrittlors. The time to failure decreased as the temperature increased toward the melting point and decreased as the applied stress was increased toward the tensile strength. Crack propagation was intergranular along the prior-austenite grain boundaries.

As with other embrittlement mechanisms, the segregation of embrittling impurities (phosphorus, antimony, arsenic, and tin) to the prior-austenite grain boundaries can influence MIE susceptibility. In an examination of the influence of prior

temper embrittlement of AISI 3340 alloy steel containing controlled additions of phosphorus, antimony, tin, and arsenic, the segregation of tin and antimony to the grain boundaries increased the susceptibility to MIE by lead or tin; however, the segregation of phosphorus and arsenic to the grain boundaries produced a minor decrease in MIE susceptibility in tests from room temperature to 425 °C (800 °F).

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Neutron Irradiation Embrittlement

The neutron irradiation of nuclear reactor components can produce an increase in strength and in the ductile-to-brittle transition temperature. The degree of irradiation-induced embrittlement depends on the neutron dose, neutron spectrum, temperature, steel composition, and heat treatment. Tempered martensite is less susceptible to neutron irradiation embrittlement than tempered bainite or ferrite-pearlite microstructures. Impurity elements in the steels can influence embrittlement; for example, phosphorus levels above 0.015% and copper levels above 0.05% are detrimental.

Radiation produces swelling and void formation. Void density decreases as the irradiation temperature increases, but the average void size increases. The examination of fractures of irradiated ferritic materials tested below their DBTT reveals a change in fracture mode from transgranular cleavage to mixed cleavage and intergranular fracture. The examination of fracture made above the DBTT reveals a change in dimple size and depth. Additional information on this subject can be found in the article "Effect of Neutron Irradiation on Properties of Steels" in this Volume.

Embrittlement of Steels

George F. Vander Voort, Carpenter Technology Corporation

Stress-Corrosion Cracking

Stress-corrosion cracking is a generic term describing the initiation and propagation of cracks in a metal or alloy under the combined action of tensile stresses (applied and/or residual) and a corrosive environment. The history of SCC failures begins in the nineteenth century with the development of cold-drawn brass cartridges for ammunition. Similar failures of brass condenser tubes brought additional attention to this problem, which soon gained the name season cracking. These failures were due to residual tensile stresses, and the benefits of stress-relieving treatments were subsequently shown. Later, the detrimental influence of ammonia on the stress-corrosion cracking of brass was observed, which led to the empirical rule of the specificity of the environment causing SCC for each alloy. This rule was cited for many years, but with subsequent research, particularly in the last 30 years, the list of environments that can cause SCC for specific alloys has grown dramatically, and the rule appears to be invalid. Also, in most cases the chemical species causing SCC need not be present in large amounts or high concentrations in the environment.

The caustic cracking of riveted boiler steels was also observed late in the nineteenth century. Caustic cracking involves a localized high concentration of free alkali at high temperatures, as would exist in a boiler. At the beginning of this century, SCC of aluminum alloys due to moisture was observed. Also, SCC of martensitic steels was encountered, but the nature of such cracks was not recognized until much later (additional information is available in the article "Wrought Stainless Steels" in this Volume). Cracking of plain carbon steels (mild steels) by nitrates was encountered in the chemical industry at the beginning of this century.

Stainless steels, first used extensively in the 1930s, were also observed to be susceptible to such failures, which were due to chlorides or caustic environments at high temperatures. Also in the 1930s, magnesium aircraft alloys were found to be susceptible to SCC caused by moisture. Cracking problems with titanium alloys were observed beginning in the 1950s.

Considerable research has been conducted on stress-corrosion cracking. Much of it has been centered on gaining an understanding of the conditions that cause it for commercial alloys and defining the influence of alloy composition, processing, and microstructure. Research has also focused on defining the mechanism(s) responsible for SCC and developing remedies to minimize or prevent SCC failures. This article concentrates on SCC of iron-base alloys, with emphasis on practical aspects rather than mechanisms. References 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, and 361 provide a wealth of additional information on stress-corrosion cracking, particularly with respect to iron-base alloys.

Properties and Conditions Producing Stress-Corrosion Cracking

A number of general characteristics of stress-corrosion cracking should be summarized before dealing with specific topics.

Alloy Susceptibility to SCC. First, the alloy must be susceptible to stress-corrosion cracking. Although it was formerly believe that pure metals are immune to SCC, recent experience has shown instances in which pure metals containing certain impurity elements were susceptible. It could be argued that such pure metals were not really pure. Also, tests of high-purity alloys have demonstrated greatly enhanced resistance to SCC even for alloys that are normally quite susceptible. Therefore, because pure is a relative term, and because the influence of impurity elements on SCC requires further study, it can be concluded that improving the purity of metals and alloys is very beneficial, but it is not yet a commercially viable solution to the SCC problem.

Static Tensile Stresses. The metal or alloy must not only be susceptible to SCC, it must also be subjected to static tensile stresses for SCC to occur. These stresses may be applied service loads, or they may result from residual stresses, or both. Stresses can also arise from the wedging action of corrosion products growing in a crack. These stresses need not exceed the yield strength of the material and can be relatively low in comparison. Generally, but not always, some stress level will exist below which cracking does not occur but above which it does (that is, a threshold stress level discussed previously in the sections "Hydrogen Damage" and "Metal-Induced Embrittlement" in this article). Compressive residual stresses, such as from shot peening, are beneficial in reducing or preventing SCC.

SCC-Inducing Chemical Species. The alloy in question must not only be under the influence of an applied or residual tensile stress of sufficient magnitude, it must also be in contact with an environment that contains a chemical species that will cause SCC. An interesting aspect of SCC is that the alloy in question is normally nearly inert, from the standpoint of general corrosion, in the environment that causes SCC. This anomalous behavior was one of the biggest surprises to early researchers who studied SCC of stainless steels because these are alloys noted for their superior corrosion resistance. Indeed, SCC failures generally show very few corrosion effects. The damaging environment, however, may produce a film on the surface of the alloy. Such films can be tarnish, passivating layers, or dealloyed layers, depending on the system. These films retard general corrosion.

As mentioned, it was believed for many years that only a few such species could cause SCC for certain alloys or families of alloys. A partial list has been compiled of species in aqueous environments that cause SCC in iron-base alloys (Table 2). As Table 2 indicates, a great many damaging environments are known (and this is only a partial list); further research will probably add to the list. Also, as previously mentioned, the damaging species does not need to be present in large quantities or high concentrations. Indeed, even parts-per-million levels have been known to cause SCC failures. Only small quantities are necessary because the damaging species can become concentrated in the affected area. Also, an environment that causes SCC in one alloy may not produce SCC in another alloy (unless they are similar in nature and composition). Similarly, a particular environment may cause SCC of an alloy only under specific conditions, such as a particular temperature, degree of aeration, or pH. A particular heat treatment or strength of the alloy could also have an impact.

Table 2 Partial list of aqueous environments known to cause stress-corrosion cracking in steels

Low-carbon steel and low-alloy ferritic steels	Austenitic stainless steels
Nitrates Phosphates Sulfates Carbonates Carbon monoxide/carbon dioxide Hydrogen sulfide Ferric chloride Ammonia Organic liquids Water/oxygen Cyanides Hydroxides	Chlorides Hydroxides Fluorides Bromides Water/oxygen Sulfates Thiocyanates Thiosulfates Tetrathionates Polythionates Sulfur dioxide Sulfurous acid

Parameters Affecting Stress-Corrosion Cracking

Variables such as temperature, pit geometry, intergranular corrosion, and slip dissolution processes can also promote stress-corrosion cracking, depending on their degree or severity.

Temperature is often a critical parameter in SCC. For some systems, failures occur only at temperatures above some specific level, and the severity or rapidity of failure increases with temperature above this limit. Chloride-induced SCC of austenitic stainless steels is known to follow this behavior.

Pit Geometry. For a smooth specimen or part under tension in an environment that can cause SCC, the process may begin with the formation of a corrosion pit. Such pits could be present on a part before it is placed in service if, for example, the part were previously excessively pickled (that is, acid cleaned). Pits may also form at inclusions that intersect the free surface of the part. Pit geometry is quite important; the pit depth must be much greater than the pit width by about a factor of ten, at a minimum. The environment within the pit must change if it is to act as a crack initiator. Not all pits initiate stress-corrosion cracks. It is possible that a preexisting pit may not develop the same electrochemical conditions as one that forms during exposure in the environment. The local chemistry in the pit appears to be important in SCC.

Intergranular Corrosion or Slip Dissolution. Stress-corrosion cracks can also initiate in the absence of pitting, for example, by slip dissolution (film rupture) processes or by intergranular corrosion. In intergranular corrosion-initiated SCC, the grain-boundary composition must differ from the bulk composition. This can occur because of the segregation of elements to the grain boundaries (or because of sensitization in austenitic stainless steels). The slip dissolution process is associated with localized corrosion on slip planes at the surface of low stacking fault energy austenitic alloys.

SCC Verification Procedures

Stress-corrosion cracking is a delayed failure process in which a certain incubation time is required to initiate cracking. The cracks propagate slowly, and propagation rates can vary from 0.1 to 10^{-9} mm/s (0.004 to 4.0×10^{-11} in./s) (Ref 358). Cracking continues until the stress exceeds the fracture strength of the remaining noncracked cross section. Crack initiation and propagation are usually divided into three stages:

- Crack initiation and stage I propagation (increasing growth rate with increasing stress intensity)
- Steady-state crack propagation (stage II: growth constant over intermediate stress intensities)
- Crack propagation to final fracture (stage III: rapid increase in crack growth rate at high stress intensities)

The threshold stress intensity necessary to produce SCC is called K_{ISCC} .

Historically, stress-corrosion cracking tests have been conducted on statically loaded smooth specimens at various stress levels, and the time to fracture is determined for specific environmental conditions. The resulting data are generally plotted on semilog paper, with the time to failure located on the log scale. Tests are conducted in relatively severe environments under the assumption that if cracking does not occur under the test conditions, the alloy is safe to use at the same stress level and temperature in a less severe environment.

Chloride cracking tests of stainless steels, for example, have been performed using boiling magnesium chloride ($MgCl_2$) solutions, which constitute a very severe environment. It is well known that the boiling point of aqueous magnesium chloride varies with the amount of magnesium chloride. This test was introduced in 1945 and is detailed in ASTM G 36. In this test, the composition is adjusted so that the solution boils at 155 ± 1 °C (311 ± 2 °F). The test must be carefully controlled because results do vary for different magnesium chloride contents and temperature.

U-Bend Testing. U-bend specimens have also been widely used to test for SCC. They exhibit large elastic and plastic strains and are a very severe test arrangement for a smooth specimen. ASTM G 30 describes the use of U-bend specimens for SCC testing.

Fracture mechanics methods are much more recent in development but are now widely used in research studies. Precracked specimens containing a sharp notch are used with either a constant applied load or a fixed crack opening displacement. Crack growth rates, da/dt , are measured as a function of the stress intensity factor, K . Tests are conducted to define the crack growth rate in stages I, II, and III and the critical threshold stress intensity level below which crack growth does not occur, K_{ISCC} . K_{ISCC} varies as a function of alloy chemistry, heat treatment, strength level, and environment.

Slow strain rate tests are also used to evaluate the SCC tendency of alloys. Either precracked or smooth specimens are used in these tests, which are conducted by slowly increasing the load or strain on the alloy. Generally, results in the detrimental environment are compared to those in an inert environment, for example, by plotting the ratios of the strains to failure, the reduction in areas, or the ultimate tensile strengths. While these are useful tests for comparing different materials or environments, they are less useful than the fracture mechanics approach for predicting in-service behavior.

SCC Evaluation of Stainless Steels

Austenitic Stainless Steels. Figure 59 shows the time to failure by SCC in boiling magnesium chloride as a function of applied stress for a variety of austenitic stainless steels (Ref 362). The families of curves shift to greater SCC resistance with increased nickel content. The 304 and 304L alloys contained 9% Ni; the 305, 309, 316, 347, and 347L alloys had nickel contents ranging from 10.5 to 13.9%; and the 310 and 314 alloys had nickel contents of 24.5 and 19.7%, respectively.

Fig. 59 Composite curves showing the relative stress-corrosion cracking resistance of standard austenitic stainless steels in boiling 42% $MgCl_2$. Source: Ref 362

The influence of nickel on stress-corrosion cracking of iron-chromium-nickel alloys has been demonstrated (Fig. 60) (Ref 363). Alloys with 8 to 77% Ni, 18 to 20% Cr, and a balance of iron were produced as wires (annealed, partially or fully hardened by drawing) and loaded in tension in boiling 42% $MgCl_2$ to determine the time to cracking with loads of 230 or 310 MPa (33 or 45 ksi). Cracking occurred most readily for alloys with about 8 to 12% Ni, and some of the 8% nickel

wires broke within 1 h. The time to cracking increased with increasing nickel content; alloys with more than approximately 45% Ni were immune to cracking.

Fig. 60 Effect of nickel content on the time to cracking for Fe-18-20Cr-Ni wires in boiling 42% MgCl₂. Source: Ref 363

The effect of composition on SCC of austenitic stainless steels, particularly in magnesium chloride solutions, has been widely studied (Ref 344, 345, 349, 350, 352, 355, 363, 364). Multiple regression analysis was used to detect compositional influences for 19 austenitic heats tested in boiling 42% MgCl₂ (Ref 364). The study concluded that the most important alloying elements were carbon and molybdenum. As these elements increased in concentration, the time to fracture passed through a minimum at about 0.065 to 0.085% C and 1.5 to 2.1% Mo. Titanium additions had only a minor influence on the effect of carbon. For the rather small nickel range studied, nickel additions had a minor beneficial influence on the time to fracture.

References 350 and 354 summarize the influence of alloying-element additions to austenitic stainless steels on their SCC behavior in chloride solutions (Fig. 61). Many alloying elements are detrimental to chloride cracking, but some are beneficial; a few have variable effects. Nickel, cadmium, zinc, silicon, beryllium, and copper are listed as being beneficial. Nickel is beneficial for resisting chloride cracking in solutions other than magnesium chloride. However, for ferritic stainless steels, small additions of nickel are detrimental to SCC resistance in chlorides. Cadmium and zinc are listed as being beneficial, but they have not been studied systematically. The influences of silicon and beryllium have been studied in some depth. Silicon additions improve the resistance to SCC in magnesium chloride, but results in sodium chloride (NaCl) at higher temperatures showed little benefit. The beneficial influence of copper is minor.

Fig. 61 Segment of periodic table showing influence of chemical element additions to austenitic stainless steels on their SCC behavior in chloride solutions. Source: Ref 350, 354

Additions of boron, aluminum, and cobalt have variable effects. Small amounts appear to be detrimental, but larger amounts appear to be helpful. Tin and manganese additions have demonstrated either no influence or detrimental or beneficial effects, depending on the amounts present. Like carbon and molybdenum, chromium additions exhibit a minimum in chloride cracking resistance, apparently at about 20%.

Crack growth rates for AISI 304L in magnesium chloride at 130 °C (265 °F) have been measured as a function of stress intensity, K (Ref 365). Figure 62 shows the results using precracked specimens. The threshold stress intensity level, K_{ISCC} , was about 8 MPa \sqrt{m} (7.3 ksi \sqrt{in}). Single cracks were observed in stage I, and branching cracks were observed in stage II.

Fig. 62 Influence of stress intensity on crack growth rate and branching of stress-corrosion cracks for AISI 304L in 42% MgCl₂ at 130 °C (265 °F). Threshold stress intensity level, K_{ISCC} , was 8 MPa \sqrt{m} (7.3 ksi \sqrt{in}). Source: Ref 265

Temperature has a very important influence on the chloride cracking of austenitic stainless steels. Experience has shown that it does not occur at room temperature. Intergranular attack was observed in severely sensitized alloys and in welded AISI 301 after a 5-year ambient temperature exposure in a marine atmosphere at Kure Beach, NC (Ref 366). Normally, chloride cracking is transgranular; however, these alloys cracked intergranularly, apparently because of the sensitization. Therefore, the failures may have been a form of intergranular stress-assisted attack, rather than true SCC (Ref 354). Chloride cracking does occur at temperatures above ambient, generally at temperatures above 60 °C (140 °F). As the temperature increases above this limit, the time to fracture decreases, other factors being constant. Additional information on the exposure of austenitic steels to marine atmospheres is available in the article "Wrought Stainless Steels" in this Volume.

Duplex stainless steels in the annealed condition are more resistant to SCC than are the common austenitic grades AISI 304 and 316. It is known that δ -ferrite in austenitic grades improves the resistance of chloride cracking. This has been attributed to the blocking of crack propagation by the δ -ferrite. Relatively high amounts (as in duplex grades) are required to be effective. Naturally, the morphology and distribution of the ferrite must be controlled in order to achieve such benefits.

An evaluation of the influence of small amounts of δ -ferrite (<10%) on SCC in 18% Cr-8% Ni grades in boiling 42% MgCl₂ found an increase in the time to fracture with increasing δ -ferrite content (Ref 367). The beneficial effect of ferrite in duplex stainless steels exposed to boiling magnesium chloride has been demonstrated (Ref 368). Figure 63 shows these results, which indicate a maximum in the time to fracture at about 40% ferrite.

Fig. 63 Effect of ferrite content on the time to failure for duplex stainless steels in boiling 42% MgCl_2 under an applied stress of 240 MPa (34.8 ksi). Source: Ref 368

Solution pH also has an influence on stress-corrosion cracking. The pH in the crack can be quite different from that of the bulk environment. Acidic conditions are required for chloride cracking, and an increase in acidity enhances SCC.

Austenitic Stainless Steels. Figure 64 shows the influence of pH on the time to fracture for AISI 304 in magnesium chloride and calcium chloride (CaCl_2) at 125 °C (255 °F). The specimens were loaded in tension at 345 MPa (50 ksi). Variations in the pH had a greater effect on magnesium chloride than on calcium chloride, and the former was a much more severe environment than the latter.

Fig. 64 Effect of solution pH on the time to failure for AISI 304 in MgCl_2 and CaCl_2 at 125 °C (255 °F) with an applied load of 345 MPa (50 ksi). Source: Ref 369

Heat-treated martensitic and precipitation-hardenable (PH) stainless steels can also fail by SCC. For these grades, the strength level has a strong influence on cracking tendency. Figure 65 shows this influence in a distilled water solution containing 0.5% acetic acid (CH_3COOH) saturated with hydrogen sulfide (H_2S), using U-bend specimens (Ref 370). For the standard martensitic grades, cracking occurred readily at hardnesses above 25 HRC; for the PH grades; cracking occurred readily above 40 HRC.

Fig. 65 Relationship between specimen hardness and time to failure in aqueous 0.5% acetic acid saturated with hydrogen sulfide for martensitic and precipitation-hardenable stainless steels. Source: Ref 370

An evaluation of AISI 410 and three PH grades (UNS S17400, S13800, and S15500) was conducted using the National Association of Corrosion Engineers (NACE) sulfide stress cracking test (5% NaCl and 0.5% acetic acid solution purged with argon to remove oxygen and saturated with hydrogen sulfide) at loads of 172, 345, or 515 MPa (25, 50, or 75 ksi) in tension (Ref 371). Figure 66 shows the time to fracture as a function of yield strength for specimens loaded at 345 MPa (50 ksi). The tempering temperature (for AISI 410) and aging treatments (for the PH grades) are shown for each strength level and alloy. The numbers in parentheses are the amount of austenite present. The alloys exhibited increased cracking resistance in the order AISI 410, S15500, S17400, S13800.

Fig. 66 Time to failure in an aqueous solution (5% NaCl and 0.5% acetic acid deaerated and saturated with hydrogen sulfide) as a function of yield strength for UNS S41000, S15500, S17400, and S13800 stainless steels loaded to 345 MPa (50 ksi) in tension. Tempering temperatures, in degrees Fahrenheit, or temper condition are shown by data points; values in parentheses are the approximate austenite contents. Source: Ref 371

Grain size differences can influence stress-corrosion cracking resistance. Studies have shown that increasing the grain size accelerates SCC, although the effect is not large, except at low applied stresses (Ref 372). Figure 67 shows the time to failure for AISI 302 wires in boiling magnesium chloride as a function of the applied stress, expressed as a percentage of the yield strength and for grain sizes of ASTM No. 5 and 9. The influence of grain size appears to be most important with regard to crack initiation, particularly for the slip dissolution mechanism.

Fig. 67 Effect of austenite grain size and applied stress as a percentage of the yield strength (311.7 and 358.5 MPa, or 45.2 and 52 ksi) for specimens with grain sizes ASTM No. 5 and No. 9, respectively, on the time to failure for AISI 302 wires in boiling 42% MgCl_2 . Source: Ref 372

Notch Toughness of Steels

G.J. Roe and B.L. Bramfitt, Bethlehem Steel Corporation

Introduction

TOUGHNESS is an indication of the capacity of a steel to absorb energy and is dependent on strength as well as ductility. Notch toughness is an indication of the capacity of a steel to absorb energy when a stress concentrator or notch is present. All carbon and high-strength low-alloy (HSLA) steels undergo a ductile-to-brittle transition as the temperature is lowered. Depending on chemical composition, product processing, and service environment, this transition can occur at temperatures from several hundred degrees above to several hundred degrees below room temperature. A number of notch impact tests have been developed to screen and rate steel product toughness on a relative basis and to determine the ductile-to-brittle transition for a specific carbon or HSLA steel product. Examples of various notch toughness tests are:

Test	ASTM specification
Charpy V-notch	E 23
Drop-weight nil-ductility	E 208
Drop-weight tear	E 436
Dynamic tear	E 604

Of all the notched tests, the most widely applied is the Charpy V-notch tests.

An illustration of a Charpy testing machine is shown in Fig. 1. The Charpy specimen shown in Fig. 2 is generally oriented so that the root of the notch lies perpendicular to the surface of the component being tested. The orientation (longitudinal or transverse) of the specimen is selected according to the appropriate product specification. The specimen is held for 10 min at the test temperature and then broken in the Charpy-type impact tester by a single blow of a freely swinging pendulum. Upon the breaking of the Charpy specimen, three criteria are commonly measured. The loss of energy in the pendulum swing provides the energy in terms of joules (foot-pounds of force) absorbed in breaking the specimen. The fracture appearance of the broken specimen can be rated in terms of ductile and brittle fracture modes. Also, the lateral expansion at the base of the fracture opposite the notch can be measured. Any of these three criteria can be plotted versus temperature to obtain a ductile-to-brittle transition curve. The most commonly used measurement is energy absorbed. For steel product specifications, a specific Charpy V-notch requirement can be negotiated between the customer and supplier (for example, a minimum energy absorbed at a specified test temperature).

Fig. 1 Typical Charpy testing machine. The coupon is chilled to the desired temperature, then quickly placed into the anvil to be broken.

Fig. 2 Charpy V-notch specimen used for the evaluation of notch toughness (ASTM E 23). Dimensions given in millimeters

Increased reliance on the Charpy test began during World War II when a number of Liberty ships experienced brittle fracture, primarily initiating at notches in the ship deck plate. The fractured plate removed from the ship met existing chemistry and strength requirements but experienced a high notch sensitivity at the ship operating temperatures. From this observation, a correlation was obtained that indicated that ship failures were not observed at temperatures where the Charpy V-notch had an absorbed energy of 20 J (15 ft · lbf) or greater. As a result of this work, the 20 J (15 ft · lbf) transition temperature requirement was established. Today Charpy requirements are used as a screening technique in

many steel applications (for example, ship-building, linepipe, highway bridges, and pressure vessel applications) where brittle fracture is a concern.

Notch Toughness of Steels

G.J. Roe and B.L. Bramfitt, Bethlehem Steel Corporation

Ductile-to-Brittle Transition

In body-centered cubic metals such as plain carbon and low-alloy steels, a unique characteristic is found during impact testing over a temperature range of approximately 120 to -130°C (250 to -200°F). This characteristic is a ductile-to-brittle transition in toughness. At the higher end of the temperature range, the fracture behavior is ductile with an accompanying large degree of plastic deformation. The ductile mode of fracture is most commonly associated with microvoid coalescence. At the lower end of the range the fracture is brittle, and the mode of the fracture is cleavage with little or no plastic deformation. Figure 3 is a Charpy curve showing a typical ductile-to-brittle transition in steel. The plot shows absorbed energy versus test temperature. The stable region at the higher temperatures is called the upper shelf, and the stable region at the lower temperatures is called the lower shelf. The region between the upper and lower shelves that displays a mixture of ductile and cleavage fracture is called the transition region.

Fig. 3 Charpy curve of impact energy versus test temperature for a nickel-chromium-molybdenum steel

Figure 4(a) shows an example of the fracture surface of a broken Charpy specimen from a low-alloy steel tested at the upper-shelf region. The absorbed energy was 117 J (86 ft · lbf). The fracture appears as a ductile, dimplelike surface with many shear lips. Inclusions, in this case titanium-nitrides (square particles) and manganese sulfides (round particles), are usually located at the center of each large dimple. These inclusions initiated the formation of a void, which created the dimple. Figure 4(b) shows the typical cleavage fracture surface at the lower-shelf region for the same steel. The absorbed energy was 6.1 J (4.5 ft · lbf). In this scanning electron microscopy (SEM) photograph, no regions of ductile tearing or shear lips are present.

Fig. 4 SEM micrographs showing the fracture surfaces of broken Charpy V-notch specimens (nickel-chromium-molybdenum steel) tested in the (a) upper-shelf region and (b) lower-shelf region of the Charpy curve shown in Fig. 3. Both 670 \times

From the Charpy curve shown in Fig. 3 a transition temperature can be determined. There are a number of criteria for transition temperature, one being the median temperature, of this transition range. In Fig. 3, this would be 25 °C (75 °F). The transition temperature could also be the temperature at a specified absorbed energy (20 J, or 15 ft · lbf, for example). Thus, in Fig. 3 the 20 J (15 ft · lbf) transition temperature would be -30 °C (-25 °F).

In addition to absorbed energy, other important measurements can be obtained from the Charpy test. For example, the lateral expansion can be measured on the broken Charpy specimen at the edge of the specimen opposite to the notch. Figure 5 shows the amount of lateral expansion one can expect at the upper- and lower-shelf regions of the Charpy curve. Lateral expansion is used as a measure of notch toughness similar to absorbed energy. Figure 6 shows a plot of lateral expansion versus test temperature for the same steel as in Fig. 3.

Fig. 5 Fracture surfaces of the broken Charpy V-notch specimens in Fig. 4. These photographs show the amount of lateral expansion in nickel-chromium-molybdenum steel specimens tested in (a) the upper-shelf region (1.5 mm, or 0.059 mil) and (b) the lower-shelf region (0.05, or 0.002 mil) of the Charpy curve shown in Fig. 3.

Fig. 6 Charpy curve of lateral expansion versus test temperature for the same nickel-chromium-molybdenum steel in Fig. 3

Another important measurement is fracture appearance transition temperature (FATT). To obtain this value, the percentage of shear (fibrous fracture) in the fracture surface is measured. The 50% FATT represents the temperature at 50% shear (50% fibrous). The 100% FATT would represent the temperature at 100% shear. Figure 7 shows a plot of percent shear versus test temperature for the same steel as in Fig. 3 and 6. From Fig. 7 the 50% FATT is 25 °C (75 °F). Note that this is the same temperature as determined from the data plotted in Fig. 3. In some steels the energy-established transition temperature and FATT may not be the same. In some steels it may be difficult to measure percent shear because of woody fracture surfaces caused by stringer-type inclusions, and so on. For these cases, it would be more appropriate to use the lateral expansion and absorbed-energy measurements to obtain a more accurate transition temperature.

Fig. 7 Charpy curve of percent shear versus test temperature for the same nickel-chromium-molybdenum steel in Fig. 3 and 6

Selection of the most appropriate method of measuring transition temperature for a given application is difficult and requires an understanding of both toughness testing and service behavior. Often, additional tests are needed to establish a correlation between the transition temperature determined using a certain method and the service behavior of a specific structure made of the same material. The method in which the impact energy at a given temperature must exceed a specific value is one method requiring such a correlation.

Despite the importance of notch toughness, other mechanical requirements must be considered, and often some compromise must be made when selecting a steel. For example, notch toughness usually decreases as carbon content, strength, and hardness are increased. Hard surfaces required for wear resistance also have an adverse effect on notch toughness.

The shape of the ductile-to-brittle transition can be represented by fitting a hyperbolic tangent curve to the data obtained from the Charpy test (Ref 1). This curve-fitting technique is now used by some design engineers to characterize and predict the toughness of a particular steel. Figure 8 shows an example of fitting a hyperbolic tangent to the set of Charpy impact data for the same steel as in Fig. 3. From this procedure, the median temperature in the transition range was calculated as 23 °C (74 °F), and the upper- and lower-shelf energies were 114 and 0.07 J (84 and 0.05 ft · lbf), respectively. Currently, the curve-fitting technique is only experimental; however, it is slowly becoming accepted by the metallurgical and materials community.

Notch Toughness of Steels

G.J. Roe and B.L. Bramfitt, Bethlehem Steel Corporation

Effects of Composition

The composition of a steel, as well as its microstructure and processing history, significantly affects both the ductile-to-brittle transition temperature range and the energy absorbed during fracture at any particular temperature. The effect of the various alloying elements and those of microstructural and processing variables are intimately interrelated; in practice, it is difficult to change one variable without affecting another (Ref 2, 3). Each individual alloying element contributes to notch toughness to varying degrees.

Carbon. Increasing carbon content increases transition temperature and decreases upper-shelf fracture energy primarily as a result of increased strength and hardness. These effects, measured by Charpy V-notch impact tests, are shown in Fig. 9. Carbon is one of the most potent alloying elements in its effect on notch toughness and strength. Consequently, for

maximum toughness, the carbon content should be kept as low as possible, consistent with strength requirements. Low-carbon steels tend to have very steep transition curves.

Fig. 9 Variation in Charpy V-notch impact energy with temperature for normalized plain carbon steels of varying carbon content. Source: Ref 4

Manganese has a variety of effects on transition temperature. In low-carbon steels, it can substantially reduce the transition temperature, as shown in Fig. 10. In higher-carbon steels, manganese may be less beneficial. As illustrated in Fig. 11, increasing the manganese content of a normalized medium-carbon steel lowered the ductile-to-brittle fracture transition temperature, probably because the additional manganese reduced the pearlite interlamellar spacing (the spacing between the alternating plates of ferrite and cementite in pearlite). In a hardened and tempered steel, manganese can have the opposite effect, as illustrated in Fig. 12. Manganese can make the steel susceptible to temper embrittlement, and it may cause the formation of less tough upper bainite (rather than fine pearlite) during normalizing (see the article "Austenitic Manganese Steels" in this Volume).

Fig. 11 Variation in Charpy V-notch impact energy with temperature for 0.30% C steels containing varying amounts of manganese. The specimens were austenitized at 900 °C (1650 °F) and cooled at approximately 14 °C/min (25 °F/min). The microstructures of these steels were pearlitic. Source: Ref 6

Fig. 12 Variation in Charpy V-notch impact energy with temperature for alloy steels containing 0.35% C, 0.35% Si, 0.80% Cr, 3.00% Ni, 0.30% Mo, 0.10% V, and the indicated amounts of manganese. The steels were hardened and tempered to a yield strength of approximately 1175 MPa (170 ksi). The microstructures of these steels contained tempered martensite. Source: Ref 7

Sulfur. The effect of sulfur on the notch toughness of steels is directly related to deoxidation practice. For rimmed, semi-killed, and silicon-killed steels, sulfur in amounts up to about 0.04% has a negligible effect on notch toughness. Sulfur has a strong directional effect on Charpy results depending on the inclusion types present (for example, sulfides, oxides, and complex nonmetallics). Charpy tests taken perpendicular to the working or rolling direction have lower absorbed energies when manganese sulfide stringers are present. Steel ladle treatments, used to reduce sulfur and to provide inclusion shape control, minimize Charpy test directionality. For silicon-aluminum-killed steels, a reduction in sulfur content can substantially increase upper-shelf energy, as shown in Fig. 13. This improvement in energy absorption results from a reduction in the number of sulfide stringers in the steel. Room-temperature Charpy results taken transverse to the rolling direction in plate steels show substantial improvement in energy absorbed only when sulfur levels are reduced below about 0.010% (Fig. 14).

Fig. 13 Variation in transverse Charpy V-notch impact energy with temperature for HSLA steels containing varying amounts of sulfur. The steels were silicon-aluminum killed with a minimum yield strength of 450 MPa (65 ksi).

Fig. 14 Effect of sulfur content on transverse impact energy at room temperature in a silicon-aluminum-killed steel

Phosphorus has a strongly deleterious effect on the notch toughness of steel. It raises the 50% FATT about 7 °C (13 °F) for each 0.01% P and reduces upper-shelf energy. In addition, phosphorus increases the susceptibility of some steels to temper embrittlement.

Silicon, used in amounts of 0.15 to 0.30% to deoxidize steels, generally lowers the ductile-to-brittle fracture transition and raises upper-shelf energy. Compared to rimmed or semikilled steels, silicon-killed steels are cleaner and have more uniform ferrite grains. These effects are probably caused by variations in steelmaking practice characteristic of the deoxidation methods used, rather than by the silicon content.

Aluminum. The effect of aluminum on the notch toughness of a medium-carbon steel is illustrated in Fig. 15. Note that increasing the aluminum content above that needed for forming aluminum nitrides ($\approx 0.075\%$ Al) impairs notch toughness.

Fig. 15 Variation in Charpy V-notch impact energy with temperature for normalized and tempered medium-carbon steels containing varying amounts of aluminum

Nitrogen, by itself, lowers the upper-shelf energy and raises the transition temperature. However, most nitrogenized steels are deoxidized with silicon and aluminum, both of which combine with nitrogen. Aluminum nitrides formed during deoxidation serve to stabilize grain size and thus improve the notch toughness of these steels.

Nickel, like manganese, is useful for improving the notch toughness of steels at low temperatures. Nickel is less effective in improving the toughness of medium-carbon steels than low-carbon steels. Some high-nickel alloy steels, such as maraging steels and austenitic stainless steels (see the articles "Maraging Steels" and "Wrought Stainless Steels" in this Volume), do not exhibit the typical ductile-to-brittle transition (austenitic steels, being face-centered cubic, do not have a ductile-to-brittle transition). The high nickel content reduces upper-shelf fracture energy—but to a level that is still quite acceptable for most applications.

Chromium raises the transition temperature slightly. In steels having chromium contents in excess of 0.90%, it is very difficult to develop those microstructures and mechanical properties that are typical of plain carbon steels; therefore, impact test results are not comparable. Chromium is usually added to increase hardenability. The increase in hardenability is often sufficient to develop a martensitic microstructure, which provides high upper-shelf energy. Medium-carbon, straight chromium alloy steels, such as 5140, are susceptible to embrittlement when quenched to martensite and tempered between 370 and 575 °C (700 and 1070 °F).

Molybdenum in the typical quantities in alloy steels (up to about 0.40%) raises the 50% FATT. Molybdenum is frequently used to increase hardenability, and it influences notch toughness primarily through its effect on microstructure. About 0.5 to 1.0% Mo can be added to alloy steels to reduce their susceptibility to temper embrittlement, but it is effective only for relatively short heating times at embrittling temperatures. Molybdenum appears to delay rather than eliminate temper embrittlement, because steels containing small amounts of this element have become embrittled upon prolonged exposure within the embrittling temperature range.

Boron. For quenched and tempered steels, a practical way of improving toughness without reducing strength is to use a boron-containing grade of steel with a lower carbon content. As shown in Fig. 16, 10B21 steel has greater toughness than 1038 steel at all strength levels. However, the benefit of boron is applicable only to quenched and tempered steels; boron reduces the toughness of as-rolled, as-annealed, and as-normalized steels.

Fig. 16 Effect of boron content on notch toughness. Room-temperature Charpy V-notch impact energy varies with tensile strength for 10B21 and 1038 steels having tempered martensite structures.

Copper in steels that have not been subjected to precipitation hardening appears to be moderately beneficial to low-temperature notch toughness. However, copper promotes precipitation hardening in steel and, as a result, may adversely affect notch toughness, particularly if the tempering temperature is between 400 and 565 °C (750 and 1050 °F).

Vanadium, niobium, and titanium are most often used in steels that receive controlled thermomechanical treatment. Consequently, the toughness of steels containing these elements is largely a function of mill processing. When the steel is finished at temperatures below about 925 °C (1700 °F) (which is characteristic of certain HSLA steels), vanadium, niobium, and titanium improve toughness primarily by refining the ferrite grain size (see the articles "High-Strength Structural and High-Strength Low-Alloy Steels" and "High-Strength Low-Alloy Steel Forgings" in this Volume). At higher finishing temperatures, these elements may be detrimental to toughness. The effect of niobium on toughness in a low-carbon normalized steel is shown in Fig. 17.

Fig. 17 Variation in Charpy V-notch impact energy with temperature for low-carbon steels containing varying amounts of niobium that were normalized from 955 °C (1750 °F). Source: Ref 8

Zirconium, titanium, calcium, and the rare earths can be used to control the shape of manganese sulfide inclusions, causing the inclusions to be spherical rather than elongated. Spherical inclusions raise upper-shelf energy and minimize the anisotropic nature of notch toughness; these effects are particularly useful in HSLA sheet and thin plate.

Interstitial elements, such as carbon, oxygen, nitrogen, and hydrogen, generally reduce the notch toughness of steels. This effect is especially evident in maraging steels, as shown in Fig. 18. Oxygen content in steels is usually determined by the deoxidation practice used in manufacturing the steel; rimmed steels have higher oxygen contents and higher transition temperatures than killed steels. Hydrogen reduces the notch toughness of steels; its chief deleterious effect occurs under conditions of slow or static loading. Specific effects are discussed in the sections "Carbon" and "Nitrogen" in this article.

Fig. 18 Effect of interstitial elements on notch toughness. The notch toughness at -18°C (0°F) of 12% Ni maraging steel can be significantly raised by controlling the amount of interstitial alloying elements in the steel, regardless of the strength level. Numbers indicate plate thickness in inches.

Antimony, Arsenic, and Tin. In trace amounts, these elements reduce the notch toughness of steels and greatly increase the susceptibility of nickel- and chromium-alloy steels to temper embrittlement.

Interactive effects of alloying elements are very common, particularly between the interstitial elements carbon and nitrogen and the strong carbide or nitride formers, such as aluminum, vanadium, manganese, niobium, molybdenum, and titanium. Some interactive effects are described in the sections "Sulfur" and "Aluminum" in this article; other examples are shown in Fig. 19 and 20. Interactive effects of alloying elements and processing variables are discussed in the next section.

Fig. 19 Interactive effect of manganese and nitrogen on notch toughness. Fracture appearance transition temperature (50% shear FATT) in plain carbon steel (0.10% C) at three manganese levels (0.4, 0.7, and 1.2% Mn) varies with nitrogen content. The beneficial effect of manganese is particularly evident at low levels of nitrogen.

Fig. 20 Interactive effect of carbon and manganese on notch toughness. Manganese-to-carbon ratio affects the transition temperature of ferritic steels. Source: Ref 6

Effects of Manufacturing Practices

The notch toughness of a steel product is the result of a number of interactive effects, including composition, deoxidation and steelmaking practices, solidification, and rolling practices, as well as the resulting microstructure. This section focuses on the general influence of manufacturing practices and the interactive effects that simultaneously influence notch toughness.

Wrought Steels

Deoxidation Practice. As a general rule, notch toughness improves from rimmed through silicon-aluminum-killed deoxidation practices. Optimum toughness is obtained in either silicon-aluminum-killed or aluminum-killed steels.

The effect of deoxidation practice on the notch toughness of steels is directly traceable to the presence of those alloying elements and impurities characteristic of the deoxidation practice. Rimmed steels typically contain appreciable quantities of oxygen and nitrogen; soundness and homogeneity of rimmed steel ingots are often poor. These characteristics of rimmed steels account for their poor notch toughness. Killed steels, particularly silicon-aluminum-killed steels, have lower transition temperatures and higher upper-shelf energy values than rimmed steels. Semikilled steels have toughness properties between those of rimmed and killed steels. A comparison of the notch toughness of these three types of steel is shown in Fig. 21. The combined effects of silicon-aluminum deoxidation and restriction of sulfur content are shown in Fig. 13. Upper-shelf energy is increased because silicon-aluminum killing reduces the incidence of detrimental silicate stringers in the steel; restriction of sulfur reduces the incidence of manganese sulfide inclusions. An aluminum killing practice reduces the inclusion levels and refines the ferrite grain size.

Fig. 21 Effects of deoxidation practice on notch toughness. Charpy V-notch impact energy varies with temperature for (a) rimmed, (b) semikilled, and (c) killed plain carbon steels.

Hot Deformation Temperature. The effect of hot deformation on the notch toughness of steel can be directly related to the microstructure produced during hot rolling and forging. Steels deformed at temperatures above about 980 °C (1800 °F) undergo considerable recrystallization and grain growth during rolling; the structure thus obtained is only slightly affected by the rolling process. The notch toughness of steels deformed at such high temperatures is largely determined by the size to which the austenite grains grow after recrystallization. The influence of grain size on transition temperature is shown in Fig. 22. When steels are deformed at lower temperatures, recrystallization and growth of austenite grains cannot proceed to the extent possible at higher deformation temperatures. Thus, the transition temperature can be significantly

lowered by deforming in the lower portion of the austenite temperature range. Figure 23 shows the effect of finishing temperature during hot rolling on the 54 J (40 ft · lbf) transition temperature of a carbon-manganese steel.

Fig. 22 Effect of grain size on notch toughness. Fracture appearance transition temperature varies with ferritic grain size of 0.11% C low-carbon steel. Transition temperature varies linearly with $\ln(d^{1/2})$ and is lower for fine-grain steel. Source: Ref 9

Fig. 23 Effect of finishing temperature on notch toughness. The 54 J (40 ft · lbf) Charpy V-notch transition temperature varies with hot-rolling finishing temperature for silicon-killed 0.24C-1.69Mn steel. Source: Ref 10

The amount of deformation at specific temperatures is also important in determining the toughness of the steel. Figure 24 illustrates the importance of sufficient reduction during rolling; although extensive rolling reduces transition temperature, it also reduces upper-shelf fracture energy. The schedule of hot-rolling temperatures and reductions is especially important for HSLA steels in order to ensure sufficient toughness and transition temperatures that are low enough. (The above discussion of hot-rolling temperature is applicable to other hot-working operations, such as extrusion or forging.)

Fig. 24 Effect of hot deformation below 900 °C (1650 °F) on 50% FATT for an HSLA steel plate

Toughness Anisotropy. Steels can acquire strongly anisotropic microstructures as a result of working. Anisotropic microstructures are often indicative of the anisotropy of mechanical properties, particularly notch toughness. Anisotropy, therefore, is an important consideration in the design and fabrication of rolled, forged, drawn, or extruded steel products.

The effect of anisotropy on the notch toughness of as-rolled low-carbon steel plate is shown in Fig. 25. Specimens parallel to the rolling direction (orientations L-S and L-T) show higher impact energies throughout the ductile-to-brittle fracture transition temperature range than do specimens perpendicular to the rolling direction (orientation T-L). Orientation L-T is the standard longitudinal specimen, and orientation T-L is the standard transverse specimen referred to in ASTM E 23. Therefore, when a part is to be cut from plate, it is essential to specify the orientation of the part relative to the rolling direction.

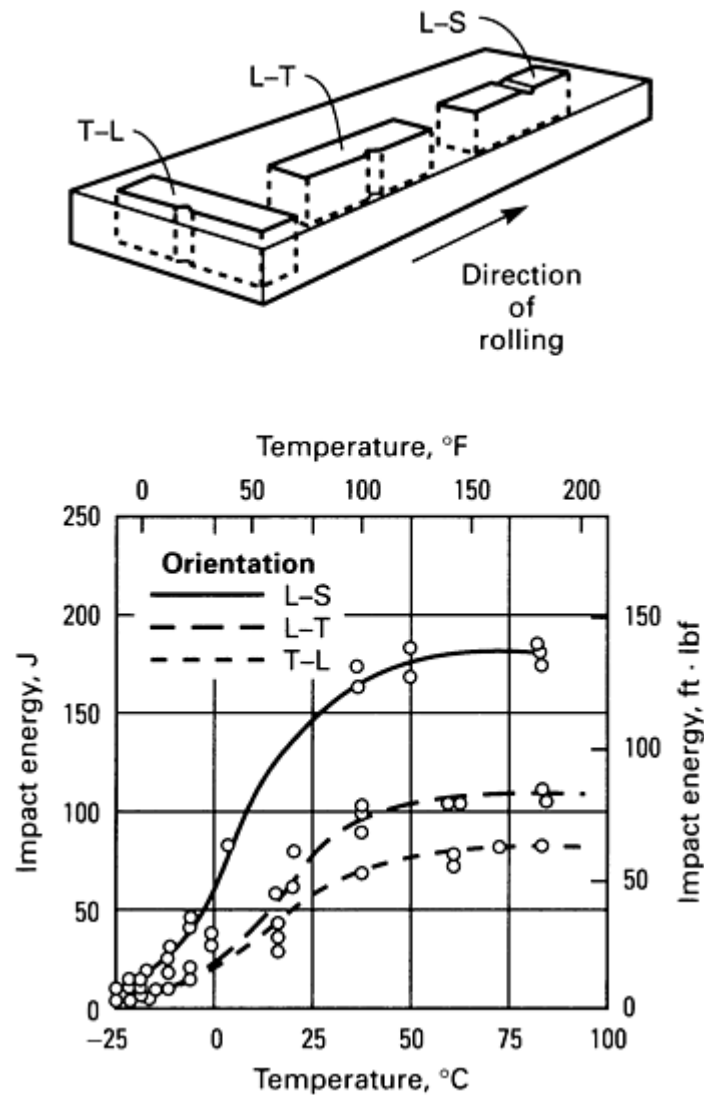

Fig. 25 Variation of Charpy V-notch impact energy with notch orientation and temperature for steel plate containing 0.012% C. Source: Ref 11

The rolling schedule during the fabrication of plate affects anisotropy. For example, if the steel had been cross rolled so that it received about the same amount of hot reduction in both directions, the curves for orientation would nearly coincide at a position between the L-T and T-L curves for material reduced by conventional rolling.

Regardless of the amount of cross rolling, specimens that are notched parallel to the plate surface (orientation L-S) absorb greater amounts of energy than those notched at right angles to the plate surface (orientation L-T). In the experiment described in Fig. 25, the temperature range over which transition occurred (and also the shear-fracture transition temperature) was the same regardless of notch or specimen orientation. In other experiments, transition temperatures for both energy absorption and fracture appearance were higher for transverse orientations than for longitudinal orientations.

Section and Part Size. Variations in fracture behavior can also result from differences in metallurgical structure between thin and thick stock of a given material. For example, the transition temperature of hot-rolled low-carbon steel varies with plate thickness, as shown in Fig. 26. In these tests, specimen size was constant, yet ductile-to-brittle energy transition still increased with increasing plate thickness. Reduction of toughness with increasing plate thickness is not limited to low-carbon steel by apparently applies to all steels. Because of the characteristics of normal commercial processing, the metallurgical structure of thick stock is different from that of thin stock, resulting in inherently lower toughness for the thicker stock. More important, the probability that a given part will contain a crack or a flaw of critical size (or greater) increases with increasing stock thickness or part size. The lower inherent toughness of thick stock and the higher probability that thick stock contains a large crack or flaw, combined with the plane-strain conditions inherent in

thick members, account for the fact that large structures are more susceptible to brittle fracture than small structures. These factors are discussed in detail in the article "Fatigue Resistance of Steels" in this Volume.

Fig. 26 Effect of plate thickness on notch toughness for aluminum semikilled steel (0.14C-1.25Mn-0.007S-0.020P-0.021Nb)

The notch toughness of steels can vary through the thickness of a plate. Pellini (Ref 12) found that the transition temperature in a thick plate was far lower near the surface than near the center of the plate (Fig. 27). Aside from problems that might be caused by inhomogeneities in mechanical properties, such a variation in toughness would be especially serious if portions of the surface of the plate were cut away, exposing the low-toughness center section to impact loading.

Fig. 27 Variation of tear test toughness with location in a plate. Variations in toughness were measured by drop-weight tear tests across the thickness of a 102 mm (4 in.) thick plate on ASTM A 387 (2.25Cr-1Mo) steel. The curve labeled $\frac{1}{4}t$ was obtained from specimens taken approximately 25 mm (1 in.) from the top and bottom surfaces of the plate.

In addition to the effects of the section size of the steel from which a part is made, the size of the part itself can influence fracture behavior. Large sections are more susceptible to brittle fracture than small sections because the large sections create conditions of plane strain under which cracks can propagate very readily.

Effects of Surface Condition on Notch Toughness. Nitriding and carburization adversely affect the notch toughness of carbon and alloy steels. Nitriding to even a relatively shallow depth (0.13 mm, or 0.005 in.) can affect notch toughness by making the surface harder and less ductile. Steel may be carburized accidentally during austenitizing under protective atmospheres; the resulting higher carbon content and hardness make the surface layer more susceptible to crack formation under impact loading.

The decrease in notch toughness that results from carburization was evaluated by heating test specimens of 1050 and 4130 steel in a carburizing atmosphere (dew point: 0 °C, or 32 °F) at 925 °C (1700 °F) for 30 min to 2 h. The specimens were quenched directly and tempered to a core hardness of 38 to 40 HRC. The decrease in notch toughness with increasing depth of carburization is shown in Fig. 28.

Fig. 28 Variation in room-temperature Charpy V-notch impact energy with depth of carburization. Specimens of 1050 and 4130 were carburized to the indicated case depth, then quenched and tempered to core hardness levels of 38 and 40 HRC, respectively.

Decarburization lowers surface hardness and permits plastic deformation at the root of a notch without crack initiation; thus, it will not lower, and may slightly increase, notch toughness. However, because decarburization adversely affects the fatigue resistance of steel, the decarburization of a notched member is rarely advisable. The effect of decarburization on notch toughness is shown in Fig. 29. Specimens of 4340 steel were deliberately decarburized during austenitizing at 820 °C (1510 °F), then quenched and tempered to a core hardness of 52 HRC. The observed values of impact energy increased slightly as the depth of decarburization increased.

Fig. 29 Variation in room-temperature notch toughness with depth of decarburization. Specimens of 4340 steel

were deliberately decarburized to the indicated depth, then hardened and tempered to 52 HRC.

Electroplating may impair notch toughness. Conventional hard plating, as with chromium or nickel, apparently has an adverse effect similar to that of carburized cases. Results from tests of specimens plated with these metals showed such wide scatter that no definite conclusions can be drawn. Hydrogen absorbed during plating may cause hydrogen embrittlement and thus contribute to the erratic results. The notch toughness of specimens plated with softer metals such as zinc and cadmium is not affected by the coating itself but may be impaired by hydrogen absorbed during plating.

Cast Steels

With the exception of working direction, most of the same chemical, microstructural, and manufacturing factors that influence the notch toughness of wrought steels also apply to cast steels. Direct comparisons are seldom made between wrought and cast steels because of differences in their chemical composition and microstructure (for example, cast steels usually contain more silicon). The porosity that sometimes occurs in cast steel may cause a greater scatter of test results than for wrought steel of similar composition. The notch toughness of cast steel is usually less than that of wrought steel measured parallel to the rolling direction but greater than that of wrought steel measured perpendicular to the rolling direction, provided the steels are otherwise similar.

To investigate the effect of melting method on the notch toughness of 0.30% C cast steels, Charpy V-notch specimens were machined from $355 \times 355 \times 38$ mm ($14 \times 14 \times 1\frac{1}{2}$ in.) plates poured from 26 production heats--9 acid electric, 9 acid open hearth, and 8 basic open hearth. All steels were fully killed with silicon and aluminum. The results of these tests, shown in Fig. 30, indicate no significant differences in notch toughness among steels melted by the three different methods. Normalizing results in an increase in notch toughness over that of annealed materials.

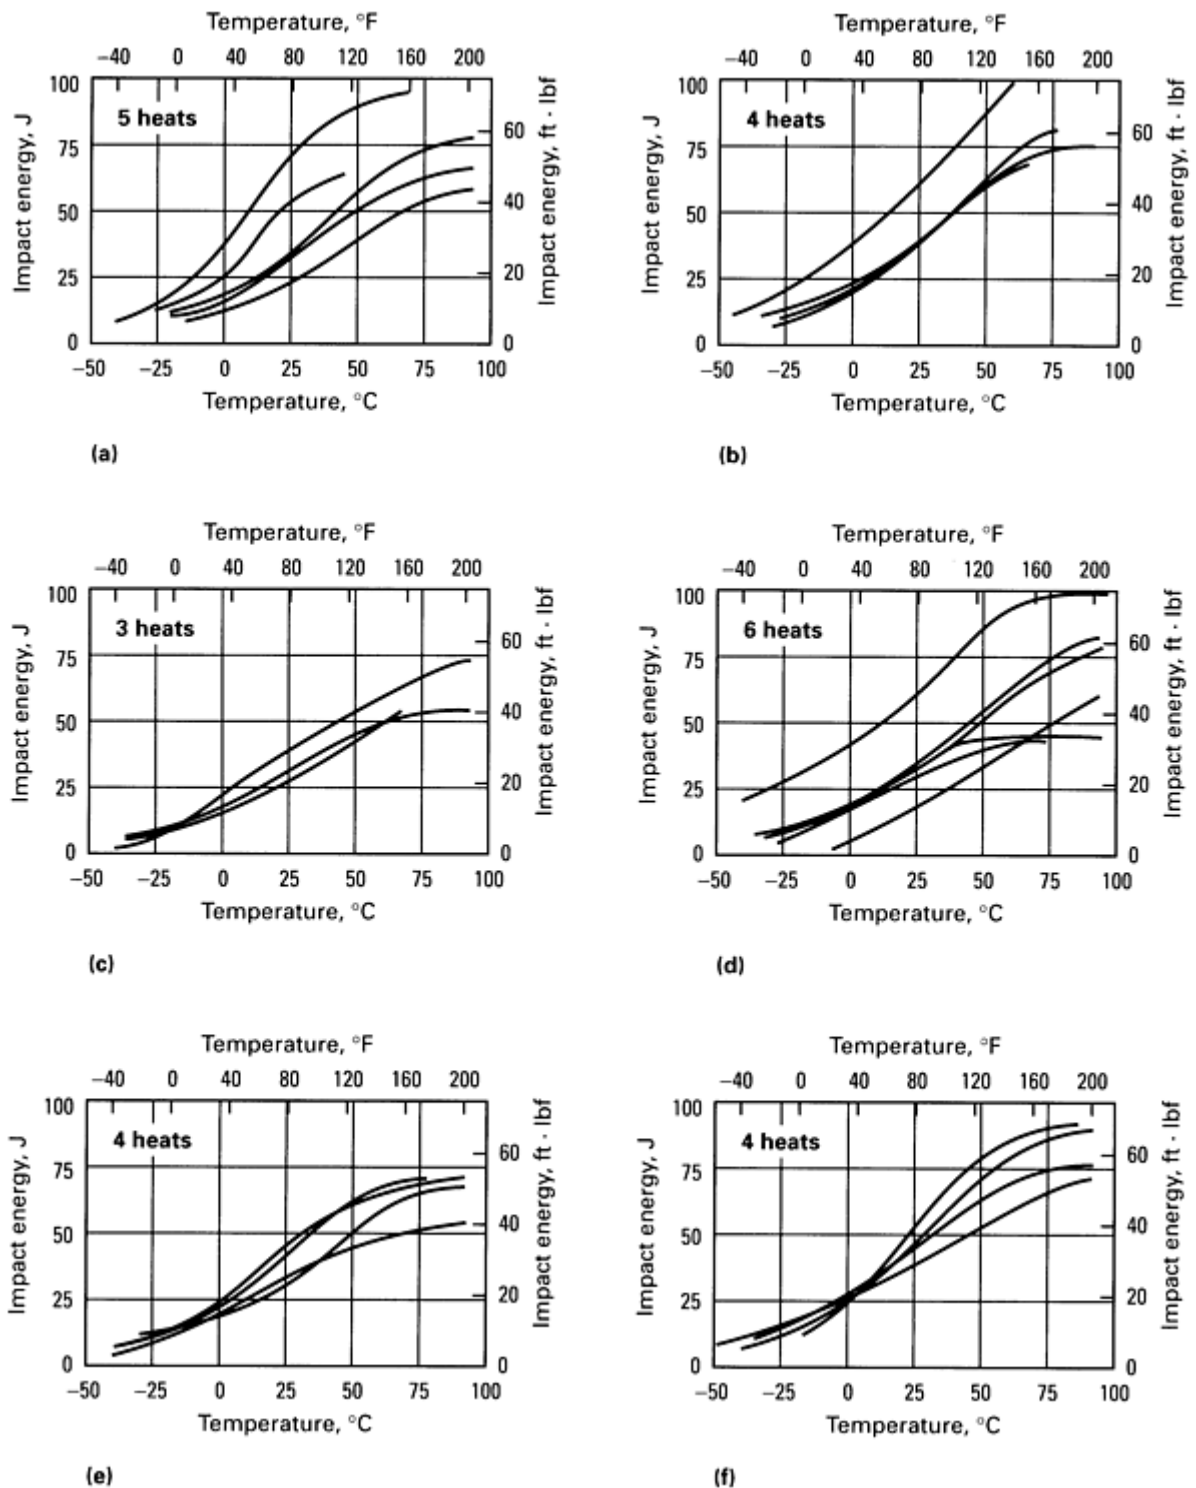

Fig. 30 Effect of melting technique on notch toughness. Variation in Charpy V-notch impact energy with temperature for annealed (a, c, and e) and normalized (b, d, and f) cast carbon steels produced using three different melting techniques. (a) and (b) 0.27C-0.70Mn-0.43Si steel melted by acid electric technique. (c) and (d) 0.29C-0.72Mn-0.44Si steel melted by acid open hearth technique. (e) and (f) 0.33C-0.78Mn-0.38Si steel melted by basic open hearth technique. All steels were fully silicon-aluminum killed.

Steel castings that have been quenched and tempered have higher notch toughness than similar castings in the as-cast, annealed, or normalized condition. The graph in Fig. 31 shows the difference in notch toughness between normalized 4330 steel and hardened and tempered 4330 steel. Despite the higher hardness of the quenched and tempered material, its upper-shelf energy is higher and its transition temperature is lower. Certain castings in the normalized condition (untempered) failed in service on excavating equipment when operated below -18°C (0°F).

Fig. 31 Effect of microstructure and hardness on notch toughness of cast steels. Charpy V-notch impact energy varies with temperature for cast 4330 steel normalized to 228 HB or hardened and tempered to 269 HB.

Carbon steel castings are sensitive to minor variations in carbon content in the same way as wrought steels. The influence of small variations in carbon is shown in Fig. 32. Additional information on the notch toughness of cast steels is available in the article "Steel Castings" in this Volume.

Fig. 32 Variation in Charpy V-notch impact energy with temperature for cast carbon steel containing different amounts of carbon, all normalized and tempered to 105 HB

Notch Toughness of Steels

G.J. Roe and B.L. Bramfitt, Bethlehem Steel Corporation

Effects of Microstructure

Like most mechanical properties, the notch toughness of steel can usually be traced directly to microstructure. Because the microstructures of steel are readily observed and classified, it is convenient to attribute the various mechanical properties to the microstructure, even though the properties might also be attributed to the composition and manufacturing history of the steel.

Microstructural Constituents

In general, of the major microstructural constituents found in steels, pearlite and ferrite have the highest transition temperature, followed by upper bainite and, finally, tempered martensite or lower bainite. Values of notch toughness for similar steels having different carbon contents and microstructural constituents are shown in Fig. 33; to facilitate comparison of the different microstructures, these steels were tempered to uniform strength levels before testing. In practice, the cooling or quenching rate determines the resulting microstructure or mixture of microstructures in a particular steel. The transformation characteristics are controlled by the cooling rate, alloy content, austenitizing temperature, and austenite grain size.

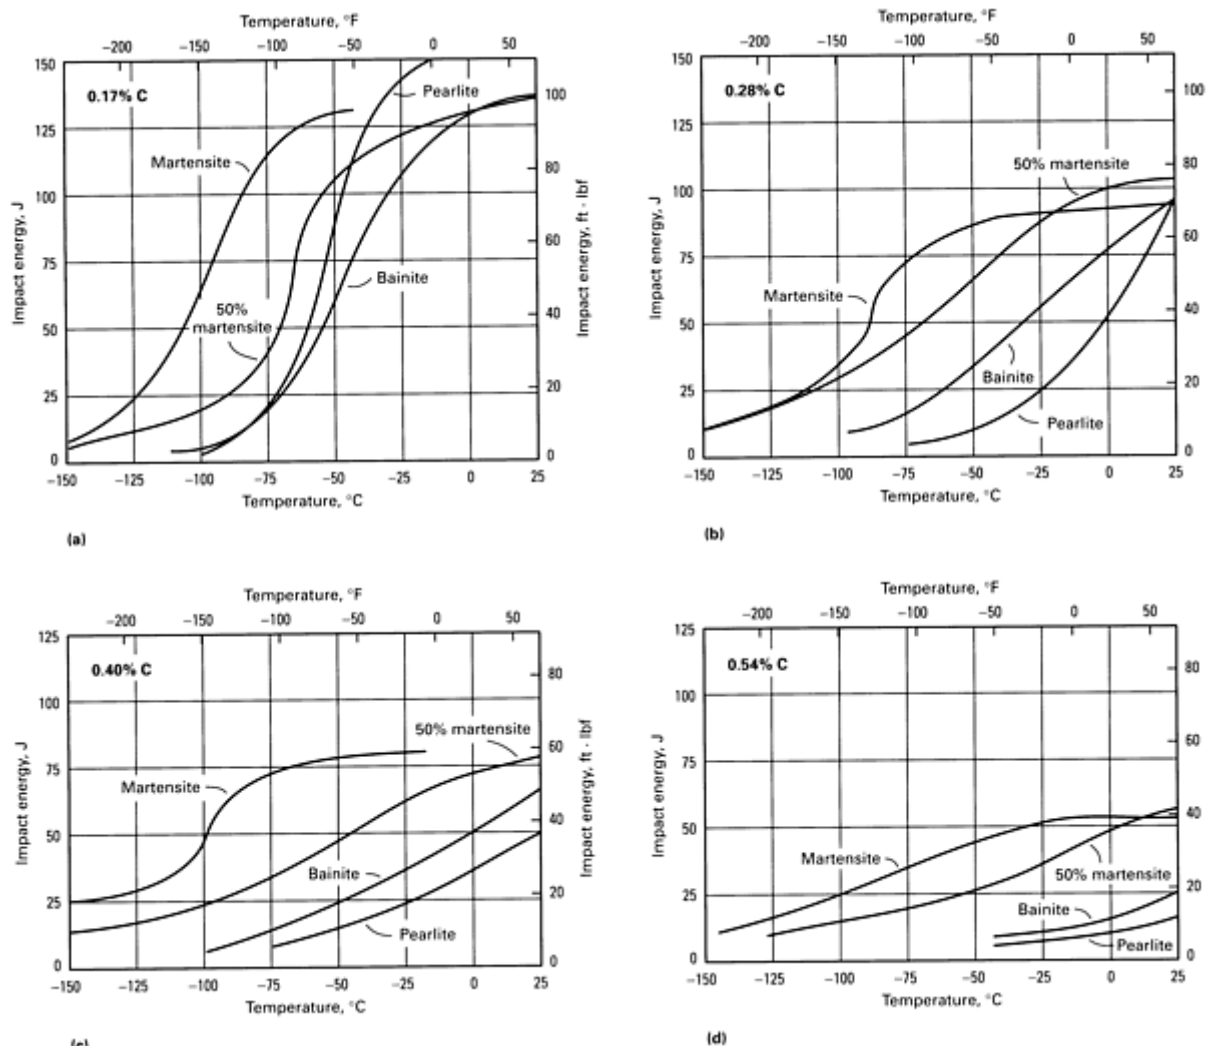

Fig. 33 Variation in Charpy V-notch impact energy with microstructure and carbon content for 0.70Cr-0.32Mo steel. Carbon content levels: (a) 0.17% C, (b) 0.28% C, (c) 0.40% C, and (d) 0.54% C. A pearlitic structure was formed by transformation at 650 °C (1200 °F). A structure with 50% martensite was formed by quenching in lead at 455 °C (850 °F) for (a) 10 s, (b) 19 s, (c) 35 s, and (d) 100 s. Fully martensitic structures were formed by quenching the 0.17 and 0.28% C grades in water and by oil quenching the grades containing 0.40 and 0.54% C. Bainite was formed by quenching in lead at 455 °C (850 °F) and holding 1 h, except that the 0.54% C grade was held 3 h. All specimens were tempered to the same hardness level.

Generally, treatments that produce microstructures with inferior room-temperature toughness also raise transition temperature. Precipitates and second-phase particles are detrimental to toughness, especially if located at grain boundaries. A spheroidization treatment of pearlitic steels can improve toughness by reducing strength and by eliminating ferrite lamellae (which have a platelike form and thus are paths of easy cleavage fracture). Spheroidization also improves toughness by changing the shape of the brittle cementite lamella of pearlite to innocuous spherical particles. In addition, steels can lose toughness because of various embrittlement phenomena such as temper embrittlement (see the section "Submicroscopic Structure" in this article).

Steels having a tempered martensitic or a lower bainitic structure offer an optimum balance of strength and toughness. When observed under a light microscope, these two microconstituents are indistinguishable. Only by transmission electron microscopy can one distinguish tempered martensite from lower bainite. Which of these two microconstituents provides better notch toughness has been a subject of controversy.

Some data indicate that lower bainite has better toughness than tempered martensite of the same strength (Fig. 34). Other data have shown the opposite effect (Ref 14). However, it is fairly well established that tempered martensite has better toughness than tempered lower bainite.

Fig. 34 Variation in Charpy V-notch impact energy with temperature for specimens of 4340 steel having 100% tempered martensite and 100% bainite microstructures. All specimens were austenitized for 30 min at 845 °C (1550 °F) in neutral salt. 100% bainite was produced by isothermal transformation for 1 h at 315 °C (600 °F) in agitated salt. 100% tempered martensite was produced by quenching in agitated oil at 50 to 55 °C (120 to 135 °F) and tempering at 315 °C (600 °F). All specimens had the same tensile strength. Source: Ref 13

The presence of austenite inhibits the fast propagation of cleavage fracture in some ferritic and martensitic steels. For example, the presence of retained austenite in martensitic maraging steel significantly improves toughness by a process called transformation-induced plasticity. The means by which toughness is improved is not fully understood, but it is thought to occur as follows (Ref 15):

- When large quantities (of the order of 50% or more) of retained austenite are present, the austenite undergoes a strain-induced transformation to martensite in the plastic region ahead of the crack tip. This consumes energy, thus raising the total energy required for the fracture process
- When austenite is retained as a lamellar phase (in lesser quantities than for a strain-induced transformation), the retained-austenite lamellae block the growth of secondary cracks in the martensite matrix just ahead of the main crack front

Additional information on the effect of the austenite-to-martensite transformation on toughness is available in the article "Maraging Steels" in this Volume.

A continuum of microstructures ranging from martensite to spheroidized cementite can be achieved by tempering martensite at various combinations of time and temperature. The notch toughness of tempered steel varies widely, from excellent to very poor. As shown in Fig. 35, tempering at higher temperatures lowers the transition temperature and raises upper-shelf energy.

Fig. 35 Variation in Charpy V-notch impact energy with temperature for various tempering temperatures. Specimens of 4340 steel were tempered 1.5 h at the indicated temperatures. Yield strength, S_Y , obtained through each heat treatment is also indicated. Source: Ref 16

Grain Size

The effect of grain size on the notch toughness of steels is mentioned in the section "Hot Deformation Temperature" in this article. Hot deformation practices can significantly affect grain size and shape. The grain size of steels can also be affected by secondary heat treatments. As shown in Fig. 22, a decrease in grain size reduces the transition temperature of steel; therefore, hot deformation practices and secondary heat treatments are usually designed to produce fine grains. In addition to improving notch toughness, a fine grain size increases the strength of steel. Thus, refinement of grain size is the most important and most effective way to increase both strength and toughness.

When steel is heated, small austenite grains form at temperatures above the temperature at which austenite begins to form upon heating. A_{c1} . Grain size continually increases with time at temperature, and higher temperatures result in faster grain growth. The strength, ductility, and impact toughness of coarse-grain metals are impaired not only by the large grain size but also by grain-boundary precipitation. Generally, when a metal has been overheated and incipient melting has not occurred, reheat treating at proper time and temperature will restore a desirable small-grain structure and satisfactory properties. The effect of normalizing at excessive temperatures is shown in Fig. 36.

Fig. 36 Variation of Charpy V-notch impact energy with temperature for low-carbon steel normalized at various temperatures

Qualitatively, the embrittling effect of large grains in ferritic steel can be explained by stress concentration at the ends of slip bands and at grain boundaries. The larger the grains, the longer the slip bands and the greater the stress concentration. Severe stress concentration will induce nucleation of microcracks, which in turn may cause early and catastrophic fracture.

Submicroscopic Structure

Several structural features that are too small to resolve by light microscopy have significant effects on the notch toughness of steels. Among these are the precipitation that occurs during quench aging or strain aging, and the brittle particles and films sometimes formed during tempering. Low (Ref 17) has shown that the ductile-to-brittle transition temperature rises abruptly with time after quenching from 690 °C (1275 °F), as illustrated in Fig. 37. Although such a quenching treatment is not common practice, it might occur inadvertently; the critical aspect of quench aging is that it continues to raise the transition temperature for a period of several years, long after the steel might have passed all of the required impact tests.

Fig. 37 Effect of aging at room temperature on the impact transition temperature of a low-carbon steel after quenching from 690 °C (1275 °F)

Strain aging is common in sheet and plate steels that have been roller straightened or stretcher straightened; strains of only a few percent can produce noticeable strain aging. Both quench aging and strain aging can be controlled by alloying with those elements that form stable carbides and nitrides, that is, elements such as niobium, titanium, and aluminum.

Medium- or high-carbon steels are susceptible to two types of embrittlement associated with the tempering of martensitic structures: blue brittleness and temper embrittlement. Both are discussed below.

Blue Brittleness. Strain aging between 230 and 370 °C (450 and 700 °F) produces blue brittleness. Medium- or high-carbon steel tempered near 300 °C (575 °F) may absorb less energy during fracture than the same steel tempered at a lower temperature—or scarcely more energy than if not tempered at all. To avoid blue brittleness, these steels usually are not tempered between 230 and 370 °C (450 and 700 °F). Tetelman and McEvily (Ref 18) reported that the deformation or testing of low-carbon steels in the blue brittleness temperature range can cause a pronounced loss of toughness. This effect is an important consideration for steels to be used between 230 and 370 °C (450 and 700 °F).

Temper embrittlement can occur if a medium- or high-carbon alloy steel is tempered between 205 and 430 °C (400 and 800 °F) or cooled slowly through that range after tempering at a higher temperature. Steels containing nickel, chromium, manganese, phosphorus, tin, arsenic, or antimony are susceptible to temper embrittlement; Fig. 38 illustrates this effect in a straight chromium steel. Controlling the amount of residual elements present in the steel—particularly phosphorus, tin, arsenic, and antimony—is effective in preventing temper embrittlement.

Fig. 38 Variation in Charpy V-notch impact energy with temperature for 5140 steel hardened and tempered at 620 °C (1150 °F). One series of specimens was quenched from tempering temperature; the other was furnace cooled. Slow cooling of susceptible steels causes temper embrittlement. Source: Ref 17

Figure 39 shows the fracture surface of a broken Charpy bar from a temper-embrittled nickel-chromium-molybdenum steel. The facets shown in the fracture are due to the intergranular failure of prior-austenite grain boundaries. The residual elements mentioned above weaken the grain boundaries and cause embrittlement. An easy way to detect temper embrittlement is to examine the fracture surface of broken Charpy specimens using scanning electron microscopy.

Notch Toughness of Steels

G.J. Roe and B.L. Bramfitt, Bethlehem Steel Corporation

Variability of Charpy Test Results

The Army Materials Testing Laboratory (formerly Watertown Arsenal Laboratory) conducted a closely controlled experiment that established the Charpy V-notch impact test as both reliable and reproducible.

Reproducibility of Test Results. A total of 1200 specimens from a single heat of aircraft quality 4340 steel were divided into three groups and heat treated to three different ranges of hardness: 43 to 46, 32.5 to 36.5, and 26 to 29 HRC. A total of 200 specimens at each hardness level were impact tested in each of two Charpy machines manufactured by two companies. The average impact energy values and distribution of results are shown in Fig. 40.

Machine	Charpy test average
---------	---------------------

	43-46 HRC, ft · lbf	32.5-36.5 HRC, ft · lbf	26-29 HRC, ft · lbf
A	12.7	48.6	78.4
B	12.6	49.1	77.9

Fig. 40 Comparison of test results from two Charpy impact machines manufactured by two companies. All 1200 specimens were made from a single heat of aircraft quality 4340 steel. Specimens were hardened and tempered to three hardness levels: 43 to 46, 32.5 to 36.5, and 26 to 29 HRC. On each of the impact machines, 200 specimens at each of the three hardness levels were tested at 20 °C (70 °F). Source: Ref 19

The test program described above clearly demonstrated the narrow spread of results that can be obtained under carefully controlled testing conditions. However, the experience of other laboratories indicates that even when the preparation and testing of impact specimens are closely controlled, a considerable spread of test results can still occur. When the effects of these variables are added to the inherent scatter that occurs among different heats of steel, the distribution of test results is broadened appreciably. Thus, judging notch toughness on the basis of one or two tests for a specific set of conditions is unwise without voluminous data on prior production heats of the material.

Some specifications designate that a specific number of specimens be tested at a particular temperature or over a particular range of temperatures. In other instances, the number of specimens with minimum or average values, or both, is negotiated. The accuracy and usefulness of results vary directly with the number of specimens tested.

Variability With Thickness and Grade. In addition to the variability in reproducibility of Charpy data during the test itself, there is variability in the steel being tested. The American Iron and Steel Institute (AISI) has conducted two extensive programs to determine the variability of Charpy impact properties in steel plates (Ref 20, 21). The combined absorbed energy and lateral expansion data from both the 1979 and 1984 survey are shown in Fig. 41 for steel grade ASTM A 572 and in Fig. 42 for steel grade ASTM A 588. The thickness range includes plates from 9.53 to 101.6 mm (0.375 to 4.0 in.) thick. For grade A 572, 99 plates are included, and for grade A 588, 57 plates are included. At each of nine test locations, three Charpy specimens were tested at -18, 4, and 21 °C (0, 40, and 70 °F). The variability for all tests and thicknesses is summarized in Table 1.

Table 1 Statistical analysis of the process variability of ASTM A 572 and A 588 high-strength low-alloy steel plates using the Charpy impact test data in Fig. 41 and 42

Correlations of Notch Toughness With Other Mechanical Properties

The Charpy test is used worldwide to indicate the ductile-to-brittle transition of a steel. While Charpy results cannot be directly applied to structural design requirements, a number of correlations have been made between Charpy results and fracture toughness.

Charpy V-Notch Correlations to Fracture Mechanics. Fracture mechanics provides a calculation of tolerable crack size and shape for a specific material application. A designer can determine the allowable crack size a structure can tolerate at a specific design stress if the fracture toughness of a steel, the operating temperature, and loading rate are known. The design criteria for highway bridge and nuclear pressure vessel steels are partially based on Charpy correlations with fracture toughness. Examples of Charpy correlations with fracture toughness parameters are given in the article "Dynamic Fracture Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

For highway bridges, the American Association of State Highway and Transportation Officials (AASHTO) has adopted minimum Charpy energy requirements based on the minimum service temperatures expected for a bridge structure. For example, a 25 mm (1 in.) thick carbon steel ASTM A 36 plate would require 34 J (25 ft · lbf) at the following Charpy test temperatures:

- 21 °C (70 °F), zone 1; minimum bridge service temperature of -18 °C (0 °F) and above
- 4 °C (40 °F), zone 2; minimum bridge service temperature of -18 to -34 °C (-1 to -30 °F)
- -12 °C (10 °F), zone 3; minimum bridge service temperature of -35 to -51 °C (-31 to -60 °F)

A bridge constructed in Florida would be in zone 1, while a northern Minnesota bridge would require zone 3 testing. These AASHTO testing requirements include a temperature shift based on the difference in loading rate between the bridge structure and the Charpy test (Ref 22).

Wrought Tool Steels

Revised by Alan M. Bayer, Teledyne Vasco, and Lee R. Walton, Latrobe Steel Company

Introduction

A TOOL STEEL is any steel used to make tools for cutting, forming, or otherwise shaping a material into a part or component adapted to a definite use. The earliest tool steels were simple, plain carbon steels, but by 1868 and

increasingly in the early 20th century, many complex, highly alloyed tool steels were developed. These complex alloy tool steels, which contain, among other elements, relatively large amounts of tungsten, molybdenum, vanadium, manganese, and chromium, make it possible to meet increasingly severe service demands and to provide greater dimensional control and freedom from cracking during heat treatment. Many alloy tool steels are also widely used for machinery components and structural applications in which particularly stringent requirements must be met, for example, high-temperature springs, ultrahigh-strength fasteners, special-purpose valves, and bearings of various types for elevated-temperature service.

In service, most tools are subjected to extremely high loads that are applied rapidly. The tools must withstand these loads a great number of times without breaking and without undergoing excessive wear or deformation. In many applications, tool steels must provide this capability under conditions that develop high temperatures in the tool. No single tool material combines maximum wear resistance, toughness, and resistance to softening at elevated temperatures. Consequently, the selection of the proper tool material for a given application often requires a trade-off to achieve the optimum combination of properties.

Most tool steels are wrought products, but precision castings can be used to advantage in some applications. The powder metallurgy (P/M) process is also used in making tool steels. It provides, first, a more uniform carbide size and distribution in large sections and, second, special compositions that are difficult or impossible to produce by melting and casting and then mechanically working the cast product.

For typical wrought tool steels, raw materials (including scrap) are carefully selected, not only for alloy content, but also for qualities that ensure cleanliness and homogeneity in the finished product. Tool steels are generally melted in relatively small-tonnage electric arc furnaces and refined in an argon oxygen decarburization (AOD) vessel to achieve composition tolerances at low cost, good cleanliness, and precise control of melting conditions. Special refining and secondary remelting processes have been introduced to satisfy particularly difficult demands regarding tool steel quality and performance. The medium-to-high alloy contents of many tool steels require careful control of forging and rolling, which often results in a large amount of process scrap. Semifinished and finished bars are given rigorous in-process and final inspection. This inspection can be so extensive that both ends of each bar may be inspected for macrostructure (etch quality), cleanliness, hardness, grain size, annealed structure, and hardening ability. Inspection may also require that the entire bar be subjected to magnetic and ultrasonic inspections for surface and internal discontinuities (see the articles "Magnetic Particle Inspection" and "Ultrasonic Inspection" in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). It is important that finished tool steel bars have minimal decarburization within carefully controlled limits, which requires that annealing be done by special procedures under closely controlled conditions.

Such precise production practices and stringent quality controls contribute to the high cost of tool steels, as do the expensive alloying element they contain. Insistence on quality in the manufacture of these specialty steels is justified, however, because tool steel bars generally are made into complicated cutting and forming tools worth many times the cost of the steel itself. Although some standard constructional alloy steels resemble tool steels in composition, they are seldom used for expensive tooling because, in general, they are not manufactured to the same rigorous quality standards as are tool steels.

The performance of a tool in service depends on the proper design of the tool, accuracy with which the tool is made, selection of the proper tool steel, and application of the proper heat treatment. A tool can perform successfully in service only when all four of these requirements have been fulfilled.

With few exceptions, all tool steels must be heat treated to develop specific combinations of wear resistance, resistance to deformation or breaking under high loads, and resistance to softening at elevated temperatures. Some tool steels are available as prehardened bar or other products. A few simple shapes may also be obtained directly from tool steel producers in correctly heat-treated condition. However, most tool steels are first formed or machined to produce the required shape and then heat treated by the tool manufacturer or ultimate user.

Wrought Tool Steels

Revised by Alan M. Bayer, Teledyne Vasco, and Lee R. Walton, Latrobe Steel Company

Classification and Characteristics

Table 1 gives composition limits for the tool steels most commonly used in 1989. Each group of tool steels of similar composition and properties is identified by a capital letter; within each group, individual tool steel types are assigned code numbers. Table 2 cross references U.S. tool steel designations with their foreign equivalents. Table 3 identifies tool steel types that have been dropped from active listings because they are no longer commonly used.

Table 1 Composition limits of principal types of tool steels

(a) Now included with D3 in Table 1.

(b) Various carbon contents were available.

Tool steels are produced to various standards including several American Society for Testing and Materials (ASTM) specifications. Reference 3 contains much useful information that essentially represents the normal manufacturing practices of most of the tool steel producers. Frequently, more stringent chemical and/or metallurgical standards are invoked by the individual producers or consumers to achieve certain commercial goals. Where appropriate, standard specifications for tool steels--ASTM A 600, A 681, and A 686--may be used as a basis for procurement. ASTM A 600 sets forth standard requirements for both tungsten and molybdenum high-speed steels; A 681 is applicable to hot-work, cold-work, shock-resisting, special-purpose, and mold steels; A 686 covers water-hardening tool steels. In many instances, however, tool steels are purchased by trade name because the user has found that a particular tool steel from a certain producer gives better performance in a specific application than does a tool steel of the same AISI type classification purchased from another source. Table 4 categorizes tool steels on the basis of specific machining applications.

Table 4 Reference guide for tool steel selection

Application areas	Tool steel groups, AISI letter symbols, and typical applications						
	High-speed tool steels, M and T	Hot-work tool steels, H	Cold-work tool steels, D, A, and O	Shock-resisting tool steels, S	Mold steels, P	Special-purpose tool steels, L	Water-hardening tool steels, W
Cutting tools Single-point types (lathe, planer, boring) Milling cutters Drills Reamers Taps Threading dies Form cutters	General-purpose production tools: M2, T1 For increased abrasion resistance: M3, M4, M10 Heavy-duty work calling for high hot hardness: T5, T15 Heavy-duty work calling for high abrasion resistance: M42, M44	...	Tools with sharp edges (knives, razors) Tools for operations in which no high speed is involved, yet stability in heat treatment and substantial abrasion resistance are needed	Pipe cutter wheels	Uses that do not require hot hardness or high abrasion resistance Examples with carbon content of applicable group: Taps (1.05-1.10% C) Reamers (1.10-1.15% C) Twist drills (1.20-1.25% C) Files (1.35-40% C)

High-Speed Steels

High-speed steels are tool materials developed largely for use in high-speed cutting tool applications. A chronology of some of the significant breakthroughs in high-speed tool steel technology is given in Table 5. There are two classifications of high-speed steel: molybdenum high-speed steels, or group M, and tungsten high-speed steels, or group T. Group M steels constitute greater than 95% of all high-speed steel produced in the United States. There is also a subgroup consisting of intermediate high-speed steels in the M group.

Table 5 Significant dates in the development of high-speed tool steels

Date	Development
1903	0.70% C, 14% W, 4% Cr prototype of modern high-speed tool steels
1904	0.30% V addition
1906	Introduction of electric furnace melting
1910	Introduction of first 18-4-1 composition (AISI T1)
1912	3-5% Co addition for improved hot hardness
1923	12% Co addition for increased cutting speeds
1939	Introduction of high-carbon, high-vanadium, super high speed tool steels (M4 and T15)
1940-1952	Increasing substitution of molybdenum for tungsten
1953	Introduction of sulfurized free-machining high-speed tool steel
1961	Introduction of high-carbon, high-cobalt, superhard high speed tool steels (M40 series)
1970	Introduction of powdered metal high-speed tool steels
1973	Addition of higher silicon/nitrogen content to M7 to increase hardness
1980	Development of cobalt-free super high speed tool steels
1982	Introduction of aluminum-modified high-speed tool steels for cutting tools

Group M and group T high-speed steels are equivalent in performance; the main advantage of the group M steels is lower initial cost (approximately 40% lower than that of similar group T steels). This difference in cost results from the lower atomic weight of molybdenum, about one-half that of tungsten. Based on weight percent, only about one-half as much molybdenum as tungsten is required to provide the same atom ratio.

Molybdenum high-speed steels and tungsten high-speed steels are similar in many other respects, including hardening ability. Typical applications for both categories include cutting tools of all sorts, such as drills, reamers, end mills, milling cutters, taps, and hobs (see the Section "Traditional Machining Processes" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Some grades are satisfactory for cold-work applications, such as cold-header die inserts, thread-rolling dies, punches, and blanking dies. Steels of the M40 series are used to make cutting tools for machining modern, very tough, high-strength steels.

For die inserts and punches, high-speed steels frequently are under hardened, that is, quenched from austenitizing temperatures lower than those recommended for cutting tool applications, as a means of increasing toughness.

Molybdenum high-speed steels contain molybdenum, tungsten, chromium, vanadium, cobalt, and carbon as principal alloying elements. Group M steels have slightly greater toughness than group T steels at the same hardness. Otherwise, mechanical properties of the two groups are similar.

Increasing the carbon and vanadium contents of group M steels increases wear resistance; increasing the cobalt content improves red hardness (that is, the capability of certain steels to resist softening at temperatures high enough to cause the steel to emit radiation in the red part of the visible spectrum) but simultaneously lowers toughness. Type M2 and other grades in the M group have unusually high resistance to softening at elevated temperatures as a result of high alloy content (Fig. 1).

Fig. 1 Variation of hardness with tempering temperature for four typical tool steels. Curves are for 1 h at temperature. Curve 1 illustrates low resistance to softening as tempering temperatures increase, such as is exhibited by group W and group O tool steels. Curve 2 illustrates medium resistance to softening, such as is exhibited by type S1 tool steel. Curves 3 and 4 illustrate high and very high resistance to softening, respectively, such as are exhibited by the secondary hardening tool steels A2 and M2.

Because group M steels readily decarburize and can be damaged from overheating under adverse austenitizing environments, they are more sensitive than group T steels to hardening conditions, particularly austenitizing temperature and atmosphere. This is especially true of high-molybdenum, low-tungsten compositions.

Group M high-speed steels are deep hardening. They must be austenitized at temperatures lower than those for hardening group T steels to avoid incipient melting. Group M high-speed steels can develop full hardness when quenched from temperatures of 1175 to 1230 °C (2150 to 2250 °F).

The maximum hardness that can be obtained in group M high-speed steels varies with composition. For those with lower carbon contents, that is, types M1, M2, M10 (low-carbon composition), M30, M33, M34, and M36, maximum hardness is usually 65 HRC. For higher carbon contents, including types M3, M4, and M7, maximum hardness is about 66 HRC. Maximum hardness of the higher-carbon cobalt-containing steels, that is, types M41, M42, M43, M44, and M46, is 69 to 70 HRC. However, few industrial applications exist for steels of the M40 series at this maximum hardness. Usually, the heat treatment is adjusted to provide a hardness of 66 to 68 HRC.

Tungsten high-speed steels contain tungsten, chromium, vanadium, cobalt, and carbon as the principal alloying elements. Type T1 was developed partly as a result of the work of Taylor and White, who in the early 1900s, found that certain steels with more than 14% W, about 4% Cr, and about 0.3% V exhibited red hardness. In its earliest form, type T1 contained about 0.68% C, 18% W, 4% Cr, and 0.3% V. By 1920, the vanadium content had been increased to about 1.0%. Over a 30-year period, the carbon content was gradually increased to its present level of 0.75%.

Group T high-speed steels are characterized by high red hardness and wear resistance. They are so deep hardening that sections up to 76 mm (3 in.) in thickness or diameter can be hardened to 65 HRC or more by quenching in oil or molten salt. The high alloy and high carbon contents produce a large number of hard, wear-resistant carbides in the microstructure, particularly in those types containing more than 1.5% V and more than 1.0% C. Type T15 is the most wear-resistant steel of this group.

The combination of good wear resistance and high red hardness makes group T high-speed steels suitable for many high-performance cutting tool applications; their toughness allows them to outperform cemented carbides in delicate tools and interrupted-cut applications. Group T high-speed steels are primarily used for cutting tools such as bits, drills, reamers, taps broaches, milling cutters, and hobs. These steels are also used for making dies, punches, and high-load high-temperature structural components such as aircraft bearings and pump parts.

Group T high-speed steels are all deep hardening when quenched from their recommended hardening temperatures of 1205 to 1300 °C (2200 to 2375 °F). They are seldom used to make hardened tools with section sizes greater than 76 mm (3 in.). Even very large cutting tools, such as drills 76 and 102 mm (3 and 4 in.) in diameter, have relatively small effective sections for hardening because metal has been removed to form the flutes. Some large-diameter solid tools are made from group T high-speed steels; these include broaches and cold extrusion punches as large as 102 to 127 mm (4 to 5 in.) in diameter.

As shown in Fig. 2, the difference between surface hardness and center hardness varies with bar size. The data in Fig. 2 are given to indicate the general trend of hardness variation rather than to provide specific values. The section size and total mass of a given tool often have an effect on its response to a given hardening treatment that is equal to or greater than the effect of the grade of tool steel selected. For tools of extremely large diameter or heavy section, it is relatively common practice to use an accelerated oil quench to provide full hardness. This practice may yield values of Rockwell C hardness only one or two points higher than those obtainable through hot-salt quenching or air cooling, which ordinarily produce full hardness in tools smaller than about 76 mm (3 in.) in diameter, but at such high hardnesses that a one- or two-point increase in Rockwell hardness may prove quite significant.

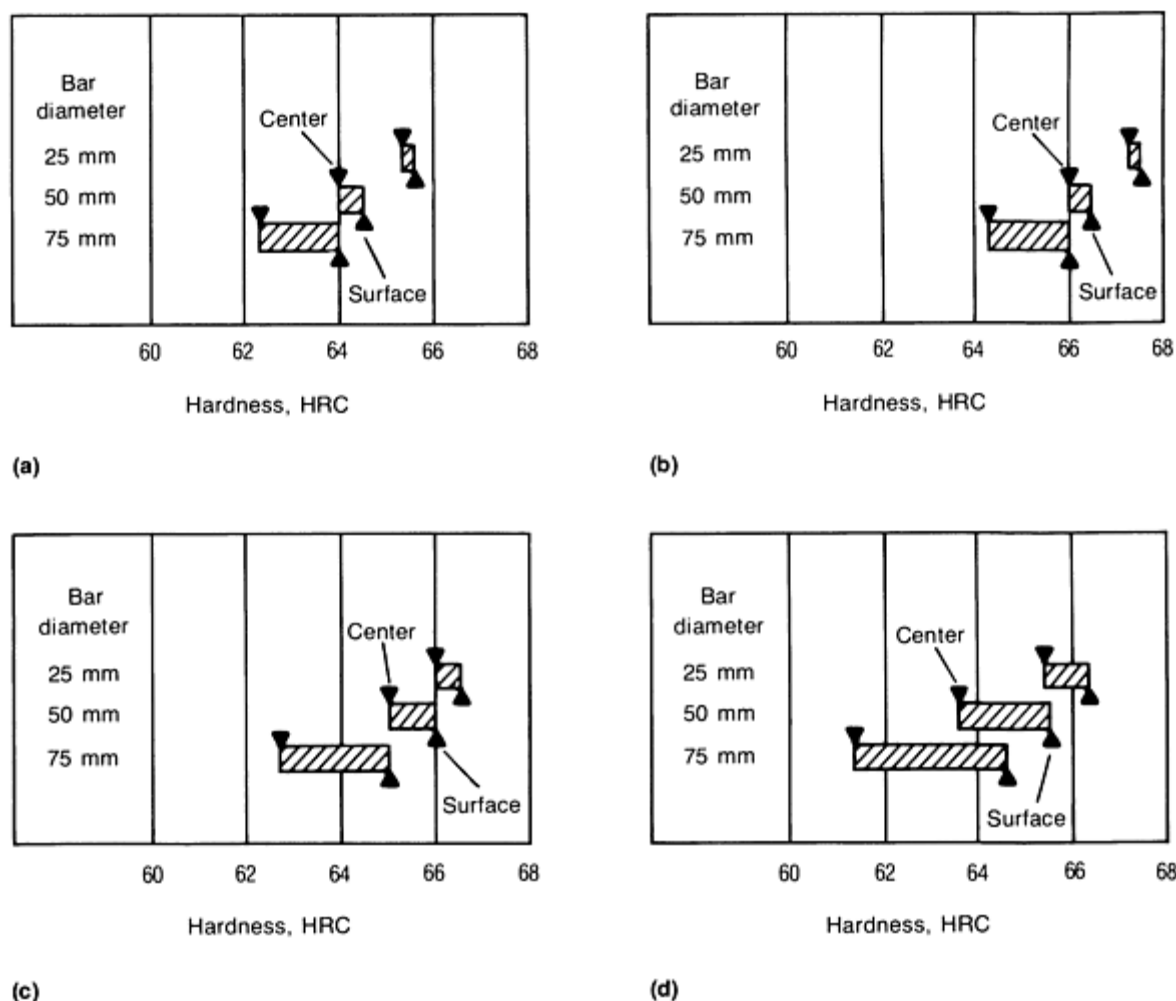

Fig. 2 Variation of surface and center hardness with bar diameter for four high-speed steels. (a) M2. (b) M3. (c) T1. (d) T2. Steels M2 and M3 were oil quenched from 1205 °C (2200 °F) and 1230 °C (2250 °F), respectively. Steels T1 and T2 were oil quenched from 1290 °C (2350 °F).

The maximum hardness of tungsten high-speed steels varies with carbon content and, to a lesser degree, with alloy content. A hardness of at least 64.5 HRC can be developed in any high-speed steel. Those types that have high carbon contents and hard carbides, such as T15, may be hardened to 67 HRC.

Hot-Work Steels

Many manufacturing operations involve punching, shearing, or forming of metals at high temperatures. Hot-work steels (group H) have been developed to withstand the combinations of heat, pressure, and abrasion associated with such operations. Table 6 gives data on resistance to softening after 100 h at temperatures from 48 to 760 °C (900 to 1400 °F) for four of these steels.

Table 6 Resistance of four hot-work steels to softening at elevated temperatures

Type	Original hardness, HRC	Hardness ^(a) , HRC, after 100 h at					
		480 °C (900 °F)	540 °C (1000 °F)	595 °C (1100 °F)	650 °C (1200 °F)	705 °C (1300 °F)	760 °C (1400 °F)

H13	50.2	48.7	45.3	29.0	22.7	20.1	13.9
	41.7	38.6	39.3	27.7	23.7	20.2	13.2
H21	49.2	48.7	47.6	37.2	27.4	19.8	15.2
	36.7	34.8	34.9	32.6	27.1	19.8	14.9
H23	40.8	40.0	40.6	40.8	38.6	33.2	25.8
	38.9	38.9	38.0	38.0	37.1	32.5	25.6

	42.9	42.4	42.3	41.3	34.9	26.4	21.1

(a) At room temperature

Group H tool steels usually have medium carbon contents (0.35 to 0.45%) and chromium, tungsten, molybdenum, and vanadium contents of 6 to 25%. H steels are divided into three subgroups: chromium hot-work steels (types H10 to H19), tungsten hot-work steels (types H21 to H26), and molybdenum hot-work steels (types H42 and H43).

Chromium hot-work steels (types H10 to H19) have good resistance to heat softening because of their medium chromium content and the addition of carbide-forming elements such as molybdenum, tungsten, and vanadium. The low carbon and low total alloy contents promote toughness at the normal working hardnesses of 40 to 55 HRC. Higher tungsten and molybdenum contents increase hot strength but slightly reduce toughness. Vanadium is added to increase resistance to washing (erosive wear) at high temperatures. An increase in silicon content improves oxidation resistance at temperatures up to 800 °C (1475 °F). The most widely used types in this group are H11, H12, H13, and, to a lesser extent, H19.

All of the chromium hot-work steels are deep hardening. The H11, H12, and H13 steels may be air hardened to full working hardness in section sizes up to 152 mm (6 in.); other group H steels may be air hardened in section sizes up to 305 mm (12 in.). The air-hardening qualities and balanced alloy contents of these steels result in low distortion during hardening. Chromium hot-work steels are especially well adapted to hot die work of all kinds, particularly dies for the extrusion of aluminum and magnesium, as well as die casting dies, forging dies, mandrels, and hot shears. Most of these steels have alloy and carbon contents low enough that tools made from them can be water cooled in service without cracking.

Tool steel H11 is used to make certain highly stressed structural parts, particularly in aerospace technology. Material for such demanding applications is produced by vacuum arc remelting of air-melted electrodes, which provides extremely low residual-gas content, excellent microcleanliness, and a high degree of structural homogeneity.

The chief advantage of H11 over conventional high-strength steels is its ability to resist softening during continued exposure to temperatures up to 540 °C (1000 °F) and at the same time provide moderate toughness and ductility at room-temperature tensile strengths of 1720 to 2070 MPa (250 to 300 ksi). In addition, because of its secondary hardening characteristic, H11 can be tempered at high temperatures, resulting in nearly complete relief of residual hardening stresses, which is necessary for maximum toughness at high strength levels. Other important advantages of H11, H12, and H13 steels for structural and hot-work applications include ease of forming and working, good weldability, relatively low

coefficient of thermal expansion, acceptable thermal conductivity, and above-average resistance to oxidation and corrosion.

Tungsten Hot-Work Steels. The principal alloying elements of tungsten hot-work steels (types H21 to H26) are carbon, tungsten, chromium, and vanadium. The higher alloy contents of these steels make them more resistant of high-temperature softening and washing than H11 and H13 hot-work steels. However, high alloy content also makes them more prone to brittleness at normal working hardnesses (45 to 55 HRC) and makes it difficult for them to be safely water cooled in service.

Although tungsten hot-work steels can be air hardened, they are usually quenched in oil or hot salt to minimize scaling. When air hardened, they exhibit low distortion. Tungsten hot-work steels require higher hardening temperatures than do chromium hot-work steels, making the former more likely to scale when heated in an oxidizing atmosphere.

Although these steels have much greater toughness, in many characteristics they are similar to high-speed steels; in fact, type H26 is a low-carbon version of T1 high-speed steel. If tungsten hot-work steels are preheated to operating temperature before use, breakage can be minimized. These steels have been used to make mandrels and extrusion dies for high-temperature applications, such as the extrusion of brass, nickel alloys, and steel, and are also suitable for use in hot-forging dies of rugged design.

Molybdenum Hot-Work Steel. There are only two active molybdenum hot-work steels: type H42 and type H43. These alloys contain molybdenum, chromium, vanadium, carbon, and varying amounts of tungsten. They are similar to tungsten hot-work steels, having almost identical characteristics and uses. Although their compositions resemble those of various molybdenum high-speed steels, they have a low carbon content and greater toughness. The principal advantage of types H42 and H43 over tungsten hot-work steels is their lower initial cost. They are more resistant to heat checking than are tungsten hot-work steels but, in common with all high-molybdenum steels, require greater care in heat treatment, particularly with regard to decarburization and control of austenitizing temperature.

Cold-Work Steels

Cold-work tool steels, because they do not have the alloy content necessary to make them resistant to softening at elevated temperature, are restricted in application to those uses that do not involve prolonged or repeated heating above 205 to 260 °C (400 to 500 °F). There are three categories of cold-work steels: air-hardening steels, or group A; high-carbon, high-chromium steels, or group D; and oil-hardening steels, or group O.

Air-hardening, medium-alloy, cold-work steels (group A) contain enough alloying elements to enable them to achieve full hardness in sections up to about 102 mm (4 in.) in diameter upon air cooling from the austenitizing temperature. (Type A6 through hardens in sections as large as a cube 178 mm, or 7 in., on a side.) Because they are air hardening, group A tool steels exhibit minimum distortion and the highest safety (least tendency to crack) in hardening. Manganese, chromium, and molybdenum are the principal alloying elements used to provide this deep hardening. Types A2, A3, A7, A8, and A9 contain a high percentage of chromium (5%), which provides moderate resistance to softening at elevated temperatures (see curve 3 in Fig. 1 for a plot of hardness versus tempering temperature for type A2).

Types A4, A6, and A10 are lower in chromium content (1%) and higher in manganese content (2%). They can be hardened from temperatures about 110 °C (200 °F) lower than those required for the high-chromium types, further reducing distortion and undesirable surface reactions during heat treatment.

To improve toughness, silicon is added to type A8, and both silicon and nickel are added to types A9 and A10. Because of the high carbon and silicon contents of type A10, graphite is formed in the microstructure; as a result, A10 has much better machinability when in the annealed condition, and somewhat better resistance to galling and seizing when in the fully hardened condition, than other group A tool steels.

Typical applications for group A tool steels include shear knives, punches, blanking and trimming dies, forming dies, and coining dies. The inherent dimensional stability of these steels makes them suitable for gages and precision measuring tools. In addition, the extreme abrasion resistance of type A7 makes it suitable for brick molds, ceramic molds, and other highly abrasive applications.

The complex chromium or chromium-vanadium carbides in group A tool steels enhance the wear resistance provided by the martensitic matrix. Therefore, these steels perform well under abrasive conditions at less than full hardness. Although

cooling in still air is adequate for producing full hardness in most tools, massive sections should be hardened by cooling in an air blast or by interrupted quenching in hot oil.

High-carbon, high-chromium, cold-work steels (group D) contain 1.50 to 2.35% C and 12% Cr; with the exception of type D3, they also contain 1% Mo. All group D tool steels except type D3 are air hardening and attain full hardness when cooled in still air. Type D3 is almost always quenched in oil (small parts can be austenitized in vacuum and then gas quenched); therefore, tools made of D3 are more susceptible to distortion and are more likely to crack during hardening.

Group D steels have high resistance to softening at elevated temperatures. These steels also exhibit excellent resistance to wear, especially type D7, which has the highest carbon and vanadium contents. All group D steels, particularly the higher-carbon types D3, D4, and D7, contain massive amounts of carbides, which make them susceptible to edge brittleness.

Typical applications of group D steels include long-run dies for blanking, forming, thread rolling, and deep drawing; dies for cutting laminations; brick molds; gages; burnishing tools; rolls; and shear and slitter knives.

Oil-hardening cold-work steels (group O) have high carbon contents, plus enough other alloying elements that small-to-moderate sections can attain full hardness when quenched in oil from the austenitizing temperature. Group O tool steels vary in type of alloy, as well as in alloy content, even though they are similar in general characteristics and are used for similar applications. Type O1 contains manganese, chromium, and tungsten. Type O2 is alloyed primarily with manganese. Type O6 contains silicon, manganese, and molybdenum; it has a high total carbon content that includes free carbon, as well as sufficient combined carbon to enable the steel to achieve maximum as-quenched hardness. Type O7 contains manganese and chromium and has a tungsten content higher than that of type O1.

The most important service-related property of group O steels is high resistance to wear at normal temperatures, a result of high carbon content. On the other hand, group O steels have a low resistance to softening at elevated temperatures.

The ability of group O steels to harden fully upon relatively slow quenching yields lower distortion and greater safety (less tendency to crack) in hardening than is characteristic of the water-hardening tool steels. Tools made from these steels can be successfully repaired or renovated by welding if proper procedures are followed. In addition, graphite in the microstructure of type O6 greatly improves the machinability of annealed stock and helps reduce galling and seizing of fully hardened steel.

Group O steels are used extensively in dies and punches for blanking, trimming, drawing, flanging, and forming. Surface hardnesses of 56 to 62 HRC, obtained through oil quenching followed by tempering at 175 to 315 °C (350 to 600 °F), provide a suitable combination of mechanical properties for most dies made from type O1, O2, or O6. Type O7, which has lower hardenability but better general wear resistance than any other group O tool steel, is more often used for tools requiring keen cutting edges. Oil-hardening tool steels are also used for machinery components (such as cams, bushings, and guides) and for gages (where good dimensional stability and wear resistance properties are needed).

The hardenability of group O steels can be measured effectively by the Jominy endquench test. Hardenability bands for group O steels are shown in Fig. 3. Variation of hardness with diameter is shown in Fig. 4 for center, surface, and $\frac{3}{4}$ radius locations in oil-quenched bars of group O steels.

Fig. 3 End-quench hardenability bands for group O tool steels. (a) O1, source A. (b) O2, source A. (c) O1 and O2, source B. (d) O6. Hardenability bands from source B represent the data from five heats each for O1 and O2 tool steels. Data from source A were determined only on the basis of average hardness, not as hardenability bands. Data for O6 is for a spheroidized prior structure. Steels O1 and O6 were quenched from 815 °C (1500 °F); O2, from 790 °C (1450 °F).

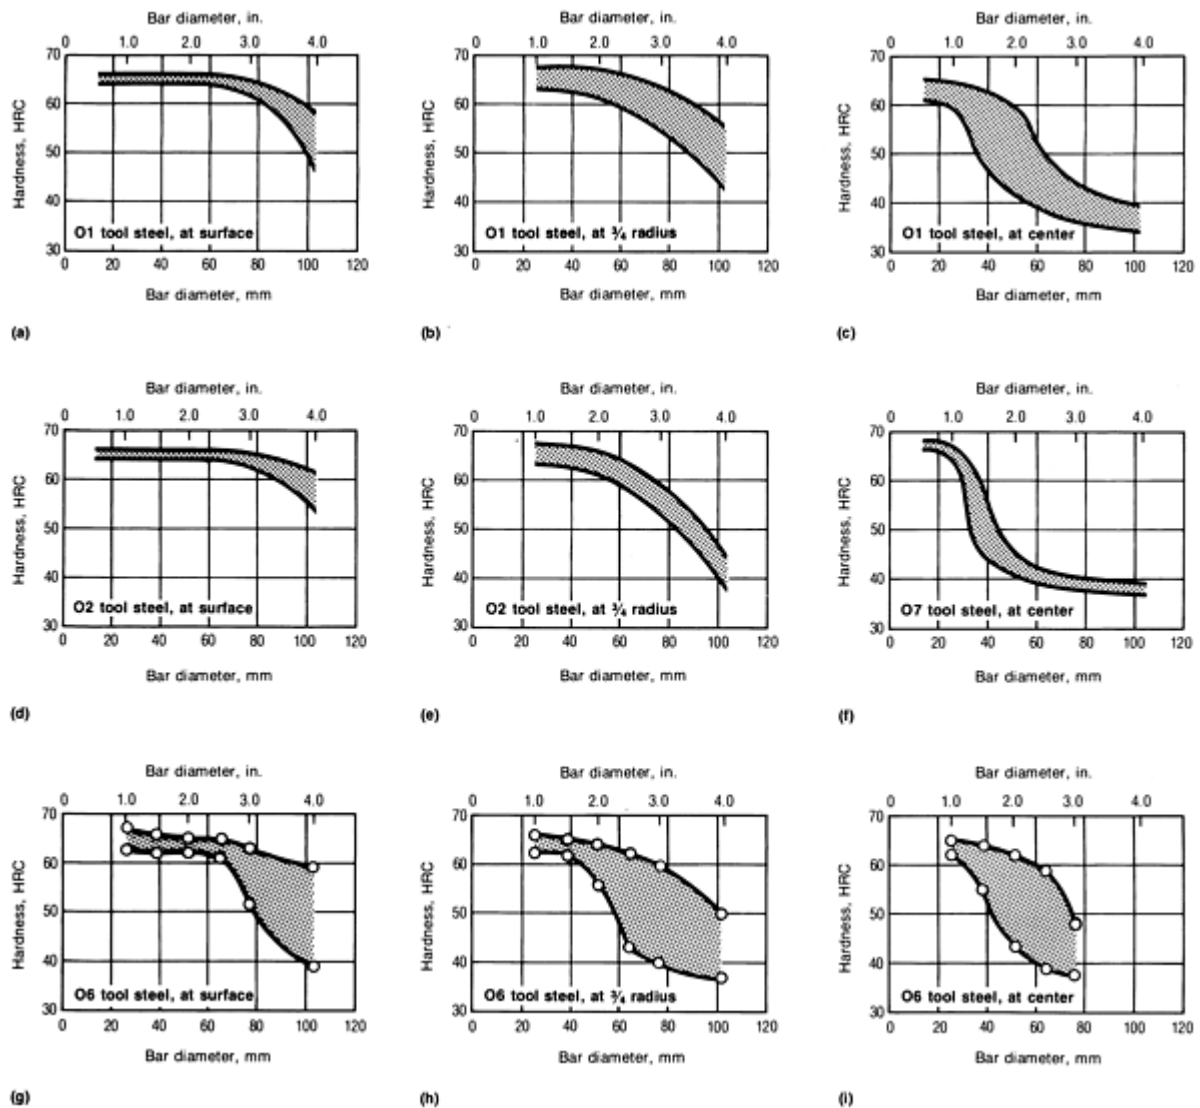

Fig. 4 Variation of as-quenched hardness with bar diameter for four oil-hardening tool steels. Data for (a), (b), (d), and (e) are from tests on 5 heats of each steel from source A. Data for (c) are from tests on 23 heats of O1 from source B. Data for (f) are from tests on 8 heats (source unknown). Information on the number of heats and source of data not available for (g), (h), and (i). Center hardness data not available for type O2; surface and $\frac{3}{4}$ -radius data not available for type O7. Type O1 austenitized at 815 °C (1500 °F) in source A and at 775 °C (1425 °F) in source B. Type O2 austenitized at 790 °C (1450 °F). Austenitizing temperatures for types O6 and O7 not available

At normal hardening temperatures, group O steels retain greater amounts of undissolved carbides and thus do not harden as deeply as do steels that are lower in carbon but similar in alloy content. On the other hand, group O steels attain higher surface hardness. Raising the hardening temperature increases grain size; increases solution of alloying elements; and dissolves more of the excess carbide, thereby increasing hardenability. However, raising the hardening temperature can have an adverse effect on certain mechanical properties, most notably ductility toughness, and also can increase the likelihood of cracking during hardening.

Shock-Resisting Steels

The principal alloying elements in shock-resisting, or group S, steels are manganese, silicon, chromium, tungsten, and molybdenum, in various combinations. Carbon content is about 0.50% for all group S steels, which produces a combination of high strength, high toughness, and low-to-medium wear resistance. Group S steels are used primarily for

chisels, rivet sets, punches, driver bits, and other applications requiring high toughness and resistance to shock loading. Types S1 and S7 are also used for hot punching and shearing, which require some heat resistance.

Group S steels vary in hardenability from shallow hardening (S2) to deep hardening (S7). In these steels of intermediate alloy content, hardenability is controlled to a greater extent by composition than by the incidental effects of grain size and melting practice, which are so important for group W steels. Group S steels require relatively high austenitizing temperatures to achieve optimum hardness; consequently, undissolved carbides are not a factor in the control of hardenability. Type S2 is normally water quenched; types S1, S5, and S6 are oil quenched; and type S7 is normally cooled in air, except for large sections, which are oil quenched.

Because group S steels exhibit excellent toughness at high strength levels, they are often considered for nontooling or structural applications. The nominal mechanical properties of S1, S5, and S7, in both annealed and hardened and tempered conditions, are presented in Table 7.

Table 7 Nominal room-temperature mechanical properties of group L and group S tool steels

Low-Alloy Special-Purpose Steels

The low-alloy special-purpose, or group L, tool steels contain small amounts of chromium, vanadium, nickel, and molybdenum. At one time, seven steels were listed in this group, but because of falling demand, only types L2 and L6 remain. Type L2 is available in several carbon contents from 0.50 to 1.10%; its principal alloying elements are chromium and vanadium, which make it an oil-hardening steel of fine grain size. Type L6 contains small amounts of chromium and molybdenum, as well as 1.50% Ni for increased toughness.

Although both L2 and L6 are considered oil-hardening steels, large sections of L2 are often quenched in water. A type L2 steel containing 0.50% C is capable of attaining about 57 HRC as oil quenched, but it will not through harden in sections of more than about 12.7 mm (0.5 in.) thickness. Type L6, which contains 0.70% C, has an as-quenched hardness of about 64 HRC; it can maintain a hardness above 60 HRC through sections of 76 mm (3 in.) thickness.

Group L steels are generally used for machine parts such as arbors, cams, chucks, and collets, and for other special applications requiring good strength and toughness. Nominal mechanical properties of annealed and hardened-and-tempered L2 and L6 steels are given in Table 7.

Mold Steels

Mold steels, or group P, contain chromium and nickel as principal alloying elements. Types P2 and P6 are carburizing steels produced to tool steel quality standards. They have very low hardness and low resistance to work hardening in the annealed condition. These factors make it possible to produce a mold impression by cold hubbing. After the impression is formed, the mold is carburized, hardened, and tempered to a surface hardness of about 58 HRC. Types P4 and P6 are deep hardening; with type P4, full hardness in the carburized case can be achieved by cooling in air.

Types P20 and P21 normally are supplied heat treated to 30 to 36 HRC, a condition in which they can be machined readily into large, intricate dies and molds. Because these steels are prehardened, no subsequent high-temperature heat treatment is required, and distortion and size changes are avoided. However, when used for plastic molds, type P20 is sometimes carburized and hardened after the impression has been machined. Type P21 is an aluminum-containing precipitation-hardening steel that is supplied prehardened to 32 to 36 HRC. This steel is preferred for critical-finish molds because of its excellent polishability.

All group P steels have low resistance to softening at elevated temperatures, with the exception of P4 and P21, which have medium resistance. Group P steels are used almost exclusively in low-temperature die casting dies and in molds for the injection or compression molding of plastics. Plastic molds often require massive steel blocks up to 762 mm (30 in.) thick and weighing as much as 9 Mg (10 tons). Because these large die blocks must meet stringent requirements for soundness, cleanliness, and hardenability, electric furnace melting, vacuum degassing, and special deoxidation treatments have become standard practice in the production of group P tool steels. In addition, ingot casting and forging practices have been refined so that a high degree of homogeneity can be achieved.

Water-Hardening Steels

Water-hardening, or group W, tool steels contain carbon as the principal alloying element. Small amounts of chromium and vanadium are added to most of the group W steels--chromium to increase hardenability and wear resistance, and vanadium to maintain fine grain size and thus enhance toughness. Group W tool steels are made with various nominal carbon contents (~0.60 to 1.40%); the most popular grades contain approximately 1.00% C.

Group W tool steels are very shallow hardening and consequently develop a fully hardened zone that is relatively thin, even when quenched drastically. Sections more than about 13 mm ($\frac{1}{2}$ in.) thick generally have a hard case over a strong, tough, and resilient core.

Group W steels have low resistance to softening at elevated temperatures. They are suitable for cold heading, striking, coining, and embossing tools; woodworking tools; hard metal-cutting tools, such as taps and reamers; wear-resistant machine tool components; and cutlery.

This group of steels is made in as many as four different grades or quality levels for the same nominal composition. These quality levels, which have been given various names by different manufacturers, range from a clean carbon tool steel with precisely controlled hardenability, grain size, microstructure, and annealed hardness to a grade less carefully controlled but satisfactory for noncritical low-production applications.

The Society of Automotive Engineers (SAE) defines four grades of plain carbon tool steels as follows:

- *Special (grade 1)*: The highest-quality water-hardening tool steel. Hardenability is controlled, and composition is held to close limits. Bars are subjected to rigorous testing to ensure maximum uniformity in performance
- *Extra (grade 2)*: A high-quality water-hardening tool steel that is controlled for hardenability and is subjected to tests that ensure good performance in general applications
- *Standard (grade 3)*: A good-quality water-hardening tool steel that is not controlled for hardenability and that is recommended for applications in which some latitude in uniformity can be tolerated
- *Commercial (grade 4)*: A commercial-quality water-hardening tool steel that is neither controlled for hardenability nor subjected to special tests

Limits on manganese, silicon, and chromium generally are not required for special and extra grades. Instead, the Shepherd hardenability limits are prescribed:

Hardenability classification	Radial depth of hardening (P), $\frac{1}{64}$ in.	Minimum fracture grain size, F
Carbon content, 0.70-0.95%		
Shallow	10 max	8
Regular	9-13	8

Deep	12 min	8
Carbon content, 0.95-1.30%		
Shallow	8 max	9
Regular	7-11	9
Deep	10-16	8

See the section "Testing of Tool Steels" in this article for more information on Shepherd hardenability.

The combined manganese, silicon, and chromium contents of SAE standard and commercial grades should not exceed 0.75%. Generally, both manganese and silicon are limited to 0.35% maximum in all standard and commercial grades; chromium is limited to 0.15% maximum in standard grades and to 0.20% maximum in commercial grades.

The ability of a group W tool steel to perform satisfactorily in many applications depends on the depth of the hardened zone. Depth of hardening in these steels is primarily controlled by the austenitic grain size, melting practice, alloy content, amount of excess carbide present at the quenching temperature and, to a lesser extent, initial structure of the steel prior to austenitizing for hardening.

Typical results in the Shepherd penetration-fracture (PF) test indicate an increase in P value of 0.8 mm ($\frac{1}{64}$ in.) for every increase in austenitic grain size of one ASTM number for the same grade. Increased amounts of undissolved carbides at the hardening temperature will reduce hardenability. This is doubly important in hypereutectoid grades, which are deliberately quenched to retain carbides undissolved at the austenitizing temperature in order to increase wear resistance. A fine lamellar microstructure prior to hardening, such as that obtained by normalizing, will result in fewer undissolved carbides at the normal austenitizing temperature than will a previously spheroidized microstructure. The presence of fewer carbides at the austenitizing temperature promotes deeper hardening because more carbon is dissolved in the austenite and there are fewer carbides to act as nucleation sites for nonmartensitic transformation products. Thus, normalized bars have deeper hardenability than do spheroidized bars of the same grade.

The addition of vanadium frequently decreases hardenability under normal hardening conditions because of the formation of many fine carbides that not only act as nucleation sites for nonmartensitic transformation products, but also refine the austenitic grain size. Austenitizing at higher-than-normal temperatures dissolves these excess carbides and thus increases the hardenability.

Group W steels with carbon contents lower than that of the eutectoid composition often have greater hardenability than do hypereutectoid grades. Grain coarsening resulting from the higher austenitizing temperatures used for hypoeutectoid grades is one cause of this, but the main cause is the absence of excess carbides at the austenitizing temperature.

Figure 5 shows a typical relationship between bar diameter and case depth (60 HRC or above) for three W1 tool steels that have the same carbon content (1% C) but different hardenabilities. Hardenability is varied by adjusting the manganese and silicon contents and altering the deoxidation procedure. This relationship illustrates the need for precise specification of hardenability in the selection of these grades: Group W tool steels purchased without hardenability requirements could vary widely enough in this property to cause severe processing difficulties or actual tool failures.

Fig. 5 Relationship of bar diameter and depth of hardened zone for shallow-, medium-, and deep-hardening grades of W1 tool steel containing 1% C

With the very fast cooling rate required for the hardening of the W grades, there is a greater chance that a tool will crack during hardening. Consequently, most manufacturers prefer to use tool steels that can be satisfactorily hardened by quenching in oil or cooling in air to attempt to avoid the expense involved when a tool cracks during heat treatment.

Wrought Tool Steels

Revised by Alan M. Bayer, Teledyne Vasco, and Lee R. Walton, Latrobe Steel Company

Typical Heat Treatments and Properties

Condensed information on heat-treating specifications and on the processing and service characteristics of tool steels is presented in Tables 8, 9, and 10. This information clarifies the problems involved in the selection, processing, and application of tool steels.

(a) O, oil quench; A, air cool; S, salt bath quench; W, water quench; B, brine quench.

(b) When the high-temperature heating is carried out in a salt bath, the range of temperatures should be about 14 °C (25 °F) lower than given here.

(c) Double tempering recommended for not less than 1 h at temperature each time.

- (d) Triple tempering recommended for not less than 1 h at temperature each time.
- (e) Times apply to open furnace heat treatment. For pack hardening, a common rule is to heat 1.2 min per mm (30 min per in.) of cross section of the pack.
- (f) Preferable for large tools to minimize decarburization.
- (g) Carburizing temperature.
- (h) After carburizing.
- (i) Carburized per case hardness.
- (j) P21 is a precipitation-hardening steel having a thermal treatment that involves solution treating and aging rather than hardening and tempering.
- (k) Recommended for large tools and tools with intricate sections

Table 10 Processing and service characteristics of tool steels

(a) A, air cool; B, brine quench; O, oil quench; S, salt bath quench; W, water quench.

(b) After tempering in temperature range normally recommended for this steel.

(c) Carburized case hardness.

(d) After aging at 510 to 550 °C (950 to 1025 °F).

(e) Toughness decreases with increasing carbon content and depth of hardening.

More detailed heat-treating information for each of these steels is available in *Heat Treating*, Volume 4 of *ASM Handbook*. Additional detailed information on resistance to softening at elevated temperatures is summarized in Fig. 1, which presents curves of hardness versus tempering temperature. Similar curves for most of the tool steels covered in this article are presented in Ref 5.

Technical representatives of tool steel producers can supply more specific information on the properties developed by specific heat treatments in the steels produced by their companies. They should be consulted regarding the type of steel and heat treatment best suited to meet all service requirements at the least overall cost.

The physical properties, specifically, density, thermal expansion, and thermal conductivity, of selected tool steels are given in Tables 11 and 12.

Wrought Tool Steels

Revised by Alan M. Bayer, Teledyne Vasco, and Lee R. Walton, Latrobe Steel Company

Testing of Tool Steels

Because of the difficulty of obtaining reliable correlations between the properties of tool steels as measured by laboratory tests and the performance of these steels in service or in fabrication, these properties are usually presented as general comparisons rather than as specific data.

Performance in Service

The basic properties of tool steels that determine their performance in service are resistance to wear, deformation, and breakage; toughness; and, in many instances, resistance to softening at elevated temperatures. These properties are listed in Table 13 and compared in Fig. 6. Often, these characteristics can be measured by, or inferred from, the measurement of hardness. The hardness of tool steels is most commonly measured and reported on the Rockwell C scale (HRC) in the United States and on the Vickers scale (diamond pyramid hardness, or HV) in Great Britain and Europe. It is significant that the conversion from HRC to HV, or vice versa, is not linear (see Fig. 7). For example, an increase from 67 to 68 HRC corresponds to a 40-point increase on the HV scale, whereas increases from 57 to 58 HRC and from 49 to 50 HRC correspond, respectively, to 20-point and 10-point increases on the HV scale.

Table 13 General properties of tool steels

Fig. 7 Relationship of Vickers and Rockwell hardness scales

Compression tests have been used to some extent to measure resistance to deformation. Bending tests using either three- or four-point supports can provide useful comparative information on tool steels with high hardness levels, but the results are often difficult to evaluate. Torsion tests have been used effectively to measure the toughness of tool steels, particularly those to be used in drills and other tools loaded in torsion during service.

The amount of energy absorbed when a notched bar of fully hardened tool steel (except for certain grades) is broken in impact (Charpy test) is so small that it is very difficult to measure the differences in toughness that may make it possible to predict service performance. Attempts have been made to perform impact tests on unnotched tool steel bars, but excessive deformation of supporting fixtures makes it very difficult to obtain reproducible results. Torsion impact testing yields useful, reproducible data on the effects of variations in the composition and heat treatment of tool steels; however,

For a given tool steel at a given hardness, wear resistance may vary widely depending on the wear mechanism involved and the heat treatment used. It is important to note also that among tool steels with widely differing compositions but identical hardnesses, wear resistance may vary widely under identical wear conditions.

For all practical purposes, the resistance to elastic deformation (modulus of elasticity) of all tool steels in all conditions is about 210 GPa (30×10^6 psi) at room temperature. This decreases uniformly to about 185 GPa (27×10^6 psi) at 260 °C (500 °F) and about 150 GPa (22×10^6 psi) at 540 °C (1000 °F).

Except for special grades, the compositions and heat treatments of most tool steels are selected to provide very high resistance to plastic deformation. This course of action leaves the metal with very little ability to absorb deformation; in other words, it leaves the metal very brittle. Therefore, it is difficult to determine reliable values of strength at maximum hardness by tensile testing, even when specially designed clamping fixtures are used to provide accurate alignment.

it is difficult to correlate the results of such testing with service experience. Fatigue tests have been useful for research, but only in some instances have the results correlated well with field experience.

In general, the ability of tool steels to withstand the rapid application of high loads without breaking increases with decreasing hardness. With hardness held constant, wide differences can be observed among tool steels of different compositions, or among steels of the same nominal composition made by different melting practices or heat treated according to different schedules.

The ability of a tool steel to resist softening at elevated temperatures is related to its ability to develop secondary hardening and to the amount of special phases, such as excess alloy carbides, in the microstructure. Useful information on the ability of tool steels to resist softening at elevated temperatures can be obtained from tempering curves such as those in Fig. 1. Hardness testing at elevated temperatures (see Fig. 8 and 9) also can provide useful information. Table 14 lists the hot hardness of selected high-speed and die steels.

(a) Small-diameter bars tested according to the recommended heat treatment.

Fig. 8 Hot hardness of H11 and T15 tool steels. Type H11 has high resistance to softening at elevated temperatures; T15 has the highest resistance to softening. For these tests, H11 was air cooled from 1010 °C (1850 °F) and tempered 2 + 2 h at 565 °C (1050 °F); T15 was oil quenched from 1230 °C (2250 °F) and tempered 2 + 2 h at 550 °C (1025 °F). After hot-hardness testing at 650 °C (1200 °F), T15 had a room-temperature hardness of 63.4 HRC.

Fabrication

The properties that influence the ease of fabrication of tool steels include machinability; grindability; weldability; hardenability; and extent of distortion, safety (freedom from cracking), and tendency to decarburize during heat treatment.

Machinability of tool steels can be measured by the usual methods applied to constructional steels. Results are reported as percentages of the machinability of water-hardening tool steels (see Table 15); 100% machinability in tool steels is equivalent to about 30% machinability in constructional steels, for which 100% machinability would be that of a free-machining, constructional steel such as B1112. Improving the machinability of a tool steel by altering either the composition or preliminary heat treatment can be very important if a large amount of machining is required to form the tool and a large number of tools are to be made.

T15	25-30
M15	25-30

(a) Equivalent to approximately 30% of the machinability of B1112.

(b) For hardness range 150 to 200 HB

Grindability. One measure of grindability is the ease with which the excess stock on heat-treated tool steel can be removed using standard grinding wheels. The grinding ratio (grindability index) is the volume of metal removed per volume of wheel wear. The higher the grindability index, the easier the metal is to grind. The index is valid only for specific sets of grinding conditions. Table 16 gives grinding ratios for several high-speed steels. It should be noted that the grindability index does not indicate the susceptibility to cracking during or after grinding, the ability to produce the required surface (and subsurface) stress distribution, or the ease of obtaining the required surface smoothness.

Table 16 Typical grinding ratios for high-speed steels using three selected grinding wheels

Type	Hardness, HRC	Grinding ratio ^(a)		
		32A46-H8VBE	32A60-H8VBE	32A80-H8VBE
T15	65.7	0.49	0.62	0.51
M44	67.7	0.97	0.99	0.88
M41	68.7	1.2	1.6	1.4

M42	68.8	4.8	6.5	3.8
M2	64.9	6.1	7.2	6.7
M1	64.9	7.8	8.0	11.9

(a) For the following conditions: work, 152 mm (6 in.) long by 38 mm (1.5 in.) wide; wheel size, 203 mm (8 in.) in diameter by 12.7 mm (0.5 in.) wide; wheel speed (idling), 30 m/s (6000 table speed, 0.3 m/s (60 sfm); unit cross feed, 1.27 mm (0.050 in.) after each table traverse; unit downfeed, 0.025 mm (0.001 in.) after each complete cross feed; total down feed, 0.25 mm (0.010 in.) preceded by four unit down feeds to break wheel in after dressing with a diamond tool; grinding fluid, 1.25% water emulsion of general-purpose soluble oil

Weldability. The ability to construct, alter, or repair tools by welding without causing the material to crack may be an important factor in the selection of a tool material, especially if the tool is large. It is only rarely of importance in selecting materials for small tools. Weldability is largely a function of composition, but welding method and procedure also influence weld soundness. Generally, tool steels that are deep hardening and that are classified as having relatively high safety in hardening are among the more readily welded tool steel compositions. These are generally the lower-alloy tool steel grades.

Hardenability includes both the maximum hardness obtainable when the quenched steel is fully martensitic and the depth of hardening obtained by quenching in a specific manner. In this context, depth of hardening must be defined, generally as a specific value of hardness or a specific microstructural appearance. As a very general rule, maximum hardness of a tool steel increases with increasing carbon content; increasing the austenitic grain size and the amount of alloying elements reduces the cooling rate required to produce maximum hardness (increases the depth of hardening). The Jominy end-quench test, which is applied extensively to measure hardenability of constructional steels (see the articles in the Section "Hardenability of Carbon and Low-Alloy Steels" in this Volume), has limited application to tool steels. This test gives useful information only for oil-hardening grades. Air-hardening grades are so deep hardening that the standard Jominy test is not sufficient to evaluate hardenability.

An air-hardenability test has been developed that is based on the principles involved in the Jominy test, but which uses only still-air cooling and a 152 mm (6 in.) diam end block to produce the very slow cooling rates of large sections. Such tests provide useful information for research but are of limited use for devising production heat treatments. By contrast, water-hardening grades of tool steel are so shallow hardening that the Jominy test is not sensitive enough. Special tests, such as the Shepherd PF test, are useful for research and for special applications of water-hardening tool steels.

In the Shepherd PF test, a bar 19 mm ($\frac{3}{4}$ in.) in diameter, in the normalized condition, is brine quenched from 790 °C (1450 °F) and fractured; the case depth (penetration, P) is measured in 0.4 mm ($\frac{1}{64}$ in.) intervals, and the fracture grain size of the case (F) is determined by comparison with standard specimens. A PF value of 6 to 8 indicates a case depth of 2.4 mm ($\frac{6}{64}$ in.) and a fracture grain size of 8. Fine-grain water-hardening tool steels are those with fracture grain sizes (F values) of 8 or more. Deep-hardening steels of this type have P values of 12 or more; medium-hardening steels, 9 to 11; and shallow-hardening steels, 6 to 8.

Distortion and Safety in Hardening. Minimal distortion in heat treating is important for tools that must remain within close size limits. In general, the amount of distortion and the tendency to crack increase as the severity of quenching increases.

Resistance to decarburization is an important factor in determining whether a protective atmosphere is required during heat treating. In a decarburizing atmosphere, the rate of decarburization increases rapidly with increasing austenitizing temperature, and, for a given austenitizing temperature, the depth of decarburization increases in direct proportion to holding time. Some types of tool steel decarburize much more rapidly than others under the same conditions of atmosphere, austenitizing temperature, and time.

Wrought Tool Steels

Revised by Alan M. Bayer, Teledyne Vasco, and Lee R. Walton, Latrobe Steel Company

Machining Allowances

The standard machining allowance is the recommended total amount of stock that the user should remove from the as-supplied mill form to provide a surface free from imperfections that might adversely affect the response to heat treatment or the ability of tools to perform properly.

The decarburization resulting from oxidation at the exposed surfaces during the forging and rolling of the tool steel is a major factor in determining the amount of stock that should be removed. Although extra care is used in producing tool steels, scale, seams, and other surface imperfections that may be present must be removed.

Table 17 gives the standard machining allowances for various sizes of hot-rolled square and flat bars. Similar tables are available for other shapes and other methods of forming and finishing in ASTM specifications A 600, A 6881, and A 686.

(a) Minimum allowance per side for machining prior to heat treatment. Maximum decarburization limit, 80% of machining allowance

In addition to the standard machining allowance, sufficient stock must be provided to permit the cleanup of any decarburization or distortion that may occur during final heat treatment. The amount varies with the type of tool steel, the type of heat treating equipment, and the size and shape of the tool.

Group W and group O tool steels are considered highly resistant to decarburization. Group M steels, cobalt-containing group T steels, group D steels, and types H42, A2, and S5 are rated poor for resisting decarburization.

Decarburization during final heat treatment is undesirable because it alters the composition of the surface layer, thereby changing the response to heat treatment of this layer and usually adversely affecting the properties resulting from heat treatment. Decarburization can be controlled or avoided by heat treating in a salt bath or in a controlled atmosphere or vacuum furnace. When heat treating is accomplished in vacuum, a vacuum of 13 to 27 Pa (100 to 200 μ m Hg) is satisfactory for most tools if the furnace is in good operating condition and has a very low leak rate. However, it is recommended that a vacuum of 7 to 13 Pa (50 to 100 μ m Hg) be used wherever possible.

If special heat-treating equipment is not available, appreciable decarburization can be avoided by wrapping the tool in stainless steel foil. Type 321 stainless steel foil can be used at austenitizing temperatures up to about 1010 °C (1850 °F); either type 309 or type 310 foil is required at austenitizing temperatures from 1010 to 1205 °C (1850 to 2200 °F).

Precision Cast Hot-Work Tools

Precision casting of tools to nearly finished size offers important cost advantages through reductions in waste and machining. Casting is a particular advantage when pattern-making costs can be distributed over a large number of tools.

Experience with cast forging and extrusion dies has shown that cast tools are more resistant to heat checking. Minute cracks do occur, but they grow at much lower rates than in wrought material of the same grade and hardness. The slower propagation of thermal-fatigue cracks generally extends die life significantly. The mechanical testing of cast and wrought H13 indicates that yield and tensile strengths are virtually identical from room temperature to 595 °C (1100 °F), but that ductility is moderately lower in cast material. Hot hardness of cast H13 is higher than that of wrought H13 at temperatures above about 315 °C (600 °F); this hardness advantage increases with temperature, as illustrated in Fig. 10, and measures about eight points on the Rockwell C scale at 650 °C (1200 °F).

Fig. 10 Comparison of hot hardness for cast and wrought H13 tool steel. Source: Latrobe Steel Company

Because cast dies exhibit uniform properties in all directions, no problem of directionality (anisotropy) exists. The dimensional control of castings is very consistent after an initial die is made and any necessary corrections are incorporated in the pattern. Reasonable finishing allowances are 0.25 to 0.38 mm (0.010 to 0.015 in.) on the impression faces, 0.8 to 1.6 mm ($\frac{1}{32}$ to $\frac{1}{16}$ in.) at the parting line of the mold, and 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) on the back and outside surfaces. The hot-work tool steels most commonly cast include H12, H13, H21, and H25.

Wrought Tool Steels

Surface Treatments

In many applications, the service life of high-speed steel tools can be increased by surface treatments.

Oxide coatings, provided by treatment of the finish-ground tool in an alkali-nitrate bath or by steam oxidation, prevent or reduce adhesion of the tool to the workpiece. Oxide coatings have doubled tool life, particularly that of tools used to machine gummy materials such as soft copper and nonfree-cutting low-carbon steels.

Plating of finished high-speed steel tools with 0.0025 to 0.0125 mm (0.1 to 0.5 mil) of chromium also prolongs tool life by reducing adhesion of the tool to the workpiece. Chromium plating is relatively expensive, and precautions must be taken to prevent tool failure in service due to hydrogen embrittlement.

Carburizing is not recommended for high-speed steel cutting tools because the cases on such tools are extremely brittle. However, carburizing is useful for applications such as cold-work dies that require extreme wear resistance and that are not subjected to impact or highly concentrated loading. Carburizing is done at 1040 to 1065 °C (1900 to 1950 °F) for short periods of time (10 to 60 min) to produce a case 0.05 to 0.25 mm (0.002 to 0.010 in.) deep. The carburizing treatment also serves as an austenitizing treatment for the whole tool. A carburized case on high-speed steels has a hardness of 65 to 70 HRC, but does not have the high resistance to softening at elevated temperatures exhibited by normally hardened high-speed steel.

Nitriding successfully increases the life of all types of high-speed steel cutting tools. However, gas nitriding in dissociated ammonia produces a case that is too brittle for most applications. Liquid nitriding for about 1 h at 565 °C (1050 °F) provides a light case, increasing both surface hardness and resistance to adhesion. For nitrided high-speed steel taps, drills, and reamers used in machining annealed steel, fivefold increases in life have been reported, with average increases of 100 to 200%. Obviously, if this nitrided case is removed when the tool is reground, the tool must then be retreated, thereby reducing the cost advantage of the process.

Other special surface treatment processes, such as aerated nitriding baths, improve resistance to adhesive wear without producing excessive brittleness. Sulfur-containing nitriding baths provide a high-sulfur surface layer for additional resistance to seizing.

Titanium nitride coating is the most common of the newer types of wear-resistant coatings that are applied to tool steels. This shallow layer of titanium nitride, formed by physical vapor deposition process, has increased tool life in many instances by as much as 400%. This is primarily attributed to the increased lubricity of the coating due to a coefficient of friction that is one-third that of the bare metal surface of the tool. This increase in tool life justifies the application of the coating, despite the increase in cost. Additional information on the benefits of titanium nitride coatings used on tool steels is available in the article "High-Speed Tools Steels" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition of *Metals Handbook*.

Sulfide Treatment. A low-temperature (190 °C, or 375 °F) electrolytic process using sodium and potassium thiocyanate provides a seizing-resistant iron sulfide layer. This process can be used as a final treatment for all types of hardened tool steels without great danger of overtempering.

Introduction

POWDER METALLURGY (P/M) has become a major process for the manufacture of high-performance tool steels and tool steel products. The items now available include as-compacted or hot-worked billets and bars, semifinished parts, near-net shapes, and indexable cutting tool inserts. The P/M process has been used primarily for the production of advanced high-speed tool steels. However, it is now also being applied to the manufacture of improved cold-work and hot-work tool steels (Ref 1, 2, 3, 4, 5).

For most applications, the P/M tool steels offer distinct advantages over conventional tool steels. As a result of pronounced ingot segregation, conventional tool steels often contain a coarse, nonuniform microstructure accompanied by low transverse properties and problems with size control and hardness uniformity in heat treatment. Rapid solidification of the atomized powders used in P/M tool steels eliminates such segregation and produces a very fine micro-structure with a uniform distribution of carbides and nonmetallic inclusions.

For high-speed tool steels, a number of important end-user properties have been improved by powder processing; notably, machinability, grindability, dimensional control during heat treatment, and cutting performance under difficult conditions where high edge toughness is essential (Ref 6). Several of these advantages also apply to P/M cold- and hot-work tool steels, which, compared to conventional tool steels, offer better toughness and ductility for cold-work tooling and better thermal fatigue life and greater toughness for hot-work tooling (Ref 2).

The alloying flexibility of the P/M process allows the production of new tool steels that cannot be made by conventional ingot processes, because of segregation-related hot-workability problems. Examples of these developments are the highly alloyed superhigh-speed steels, such as CPM Rex 20, CPM Rex 76, and ASP 60, and the highly wear resistant cold-work tool steels, such as CPM 9V and CPM 10V.

As shown in Fig. 1, there are a large number of possibilities for powder production, shape making, and powder consolidation. The options shown in Fig. 1 are by no means complete because new processes are continuously being developed. However, because tool steels are highly stressed in service, the usual production routes applicable to P/M tooling are those that yield a fully dense, pore-free structure. Any remaining porosity in such products has been shown to act as a local stress raiser and to initiate premature failure (Ref 8, 9).

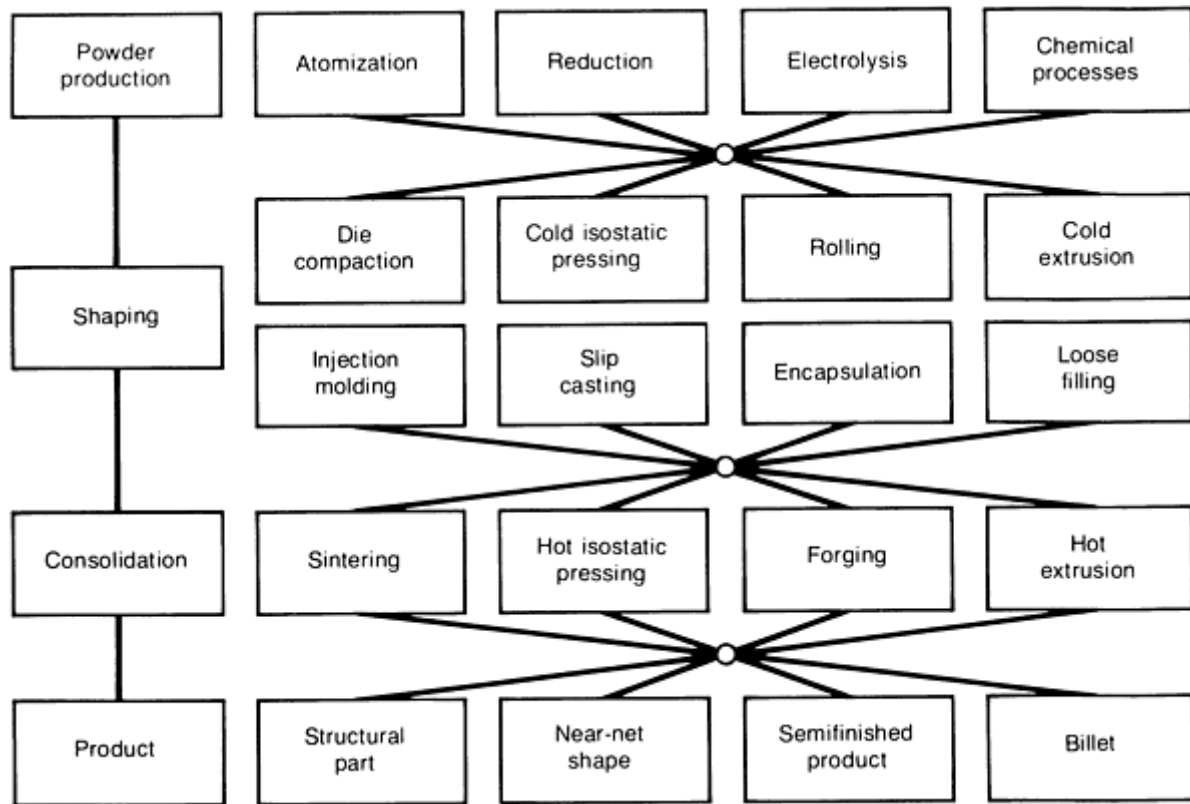

Fig. 1 P/M production methods. Source: Ref 7

The basic production routes now in commercial use for P/M tool steels are summarized in Fig. 2. All these processes use gas-or water-atomized powders and either hot isostatic pressing (HIP), mechanical compaction (extrusion), forging, and so on), or vacuum sintering for densification (Ref 10). The basic difference among these processes is that the use of gas atomization will yield spherical particles, while water atomization will produce angular particles of significantly higher oxygen content. The angular particles can be cold pressed to provide a compact that has sufficient mechanical strength to be handled and processed directly, while the spherical gas-atomized powder must be encapsulated prior to densification.

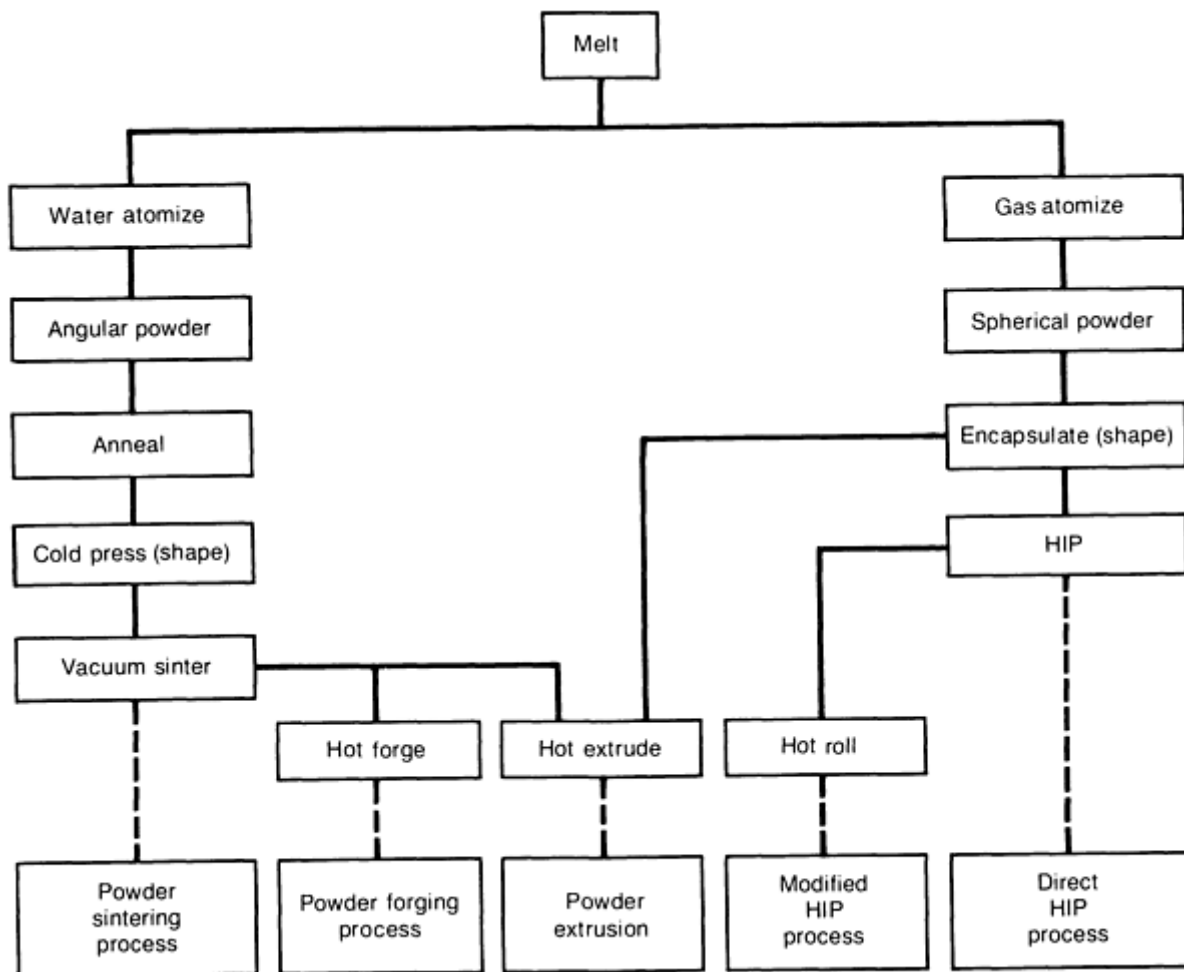

Fig. 2 Current manufacturing processes for P/M tool steels. Source: Ref 10

The most widely used production practices for P/M tool steels utilize gas atomization and hot isostatic compaction and include the Anti-Segregation process (ASP), developed in Sweden by Stora Kopparberg and ASEA (Ref 11), and the Crucible Particle Metallurgy (CPM) process, developed in the United States by the Crucible Materials Corporation (Ref 12). Other processes using gas-atomized powders involve compaction at atmospheric pressure (CAP process), high-pressure compaction and hot working (STAMP process), and controlled spray deposition and hot working (CSD and Osprey) (Ref 13, 14, 15, 16).

Most of the processes that use water-atomized powders utilize vacuum sintering for compaction and are used to produce complex tool shapes and indexable cutting tool inserts. They include the Powdrex process developed in the United Kingdom by Powdrex, Ltd. (Ref 17), and the full densification FULDENS process, developed in the United States by Consolidated Metallurgical Industries, Inc. (Ref 18) and currently licensed by Krupp Engineering, Inc. Additional information on the processes available for the production of P/M tool steels is given in the references at the end of this article and in *Powder Metallurgy Technologies and Applications*, Volume 7, and *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

P/M High-Speed Tool Steels

A large variety of P/M high-speed tool steels are available (Table 1). The P/M process has been applied primarily to standard American Iron and Steel Institute (AISI) high-speed tool steels (M2, M3, M4, M35, and so on) that are normally produced by conventional means but have significantly improved toughness and grindability when the P/M process is used. Highly resulfurized grades, such as M2HCHS and M3HCHS, also offer improved machinability when produced by this process. Other grades that are very difficult to produce by conventional means are readily produced by the P/M process, with an accompanying improvement in properties. Still others, such as CPM Rex 20, CPM Rex 76, and ASP 60, represent superhigh-speed steels that are very difficult to produce by conventional means and are made only by P/M processing.

(a) HCHS, high carbon, high sulfur; HS, high sulfur

A distinguishing feature of P/M high-speed tool steels is the uniform distribution and small size of the primary carbides. The same is true of the sulfide inclusions in resulfurized grades. The size distributions of the primary carbides in P/M-produced and conventionally produced T15 have been measured, as shown in Fig. 3. Most of the carbides in CPM high-speed tool steels are less than about 3 μm (120 $\mu\text{in.}$), while those in the conventional product cover the entire size range up to about 34 μm (1360 $\mu\text{in.}$), with a median size of 6 μm (240 $\mu\text{in.}$). Microstructures of CPM and conventionally processed T15 are shown in Fig. 4.

Fig. 3 Primary carbide size distributions in CPM and conventionally produced T15 high-speed tool steel

Fig. 4 Microstructures of high-speed tool steels. Left: CPM T15. Right: Conventional T15. Carbide segregation and its detrimental effects are eliminated with the CPM process, regardless of the size of the products. Courtesy of Crucible Materials Corporation

Heat Treatment

Proper heat treatment of tool steels is essential for developing their properties. This is especially true of high-speed and high-alloy materials. Improper heat treatment of these steels can result in a tool with greatly reduced properties or even one that is unusable. Powder metallurgy tool steels utilize the same basic heat treatments as their conventional counterparts, but they tend to respond more rapidly and with better predictability to heat treatment because of their more uniform microstructure and finer carbide size. The basic heat treatments used include preheating, austenitizing, quenching, and tempering. However, optimum heat-treating temperatures may vary somewhat, even if chemical compositions are identical.

The following procedures are specific to ASP high-speed tool steels, but are generally applicable to all P/M high-speed tool steels. Deviations from these practices may be needed for some specific alloys and applications; in such cases, the recommendations by the manufacturer should be followed. The basic heat treatment steps are:

- **Annealing:** Heat to 850 to 900 °C (1560 to 1650 °F). Slow cool 10 °C/h (18 °F/h) to 700 °C (1290 °F).

Typical annealed hardness values for ASP 23 are about 26 HRC maximum, 32 HRC for ASP 30, and 36 HRC for ASP 60

- *Stress relieving (before hardening)*: Hold for approximately 2 h at 600 to 700 °C (1110 to 1290 °F). Slow cool to 500 °C (930 °F) in furnace
- *Hardening*: Preheat in two steps, first at 450 to 500 °C (840 to 930 °F) and then at 850 to 900 °C (1560 to 1650 °F). Austenitize at 1050 to 1180 °C (1920 to 2155 °F) and quench, preferably in neutral salt baths. Cool to hand warmth. See Table 2 for recommended austenitizing temperatures
- *Tempering*: Raise temperature to 560 °C (1040 °F) or higher. Repeat two or three times for at least 1 h at full temperature. Cool to room temperature between tempers

The hardnesses of three P/M high-speed tool steels after hardening and tempering are shown in Fig. 5.

Table 2 Austenitizing temperatures of ASP 23 steel

Hardness, HRC ^(a)	Temperature		Salt bath ^(b)		Other furnace, min ^(c)
	°C	°F	min/mm	min/in.	
58	1000	1830	0.59	15	30
60	1050	1925	0.47	12	25
62	1100	2010	0.39	10	20
64	1140	2085	0.31	8	15

(a) After triple temper at 560 °C (1040 °F); hardness values may vary by $\pm 1\%$.

(b) Total immersion time after preheating.

(c) Holding time in minutes after tool has reached full temperature

Fig. 5 Hardness of ASP steels after hardening and tempering a 25 mm (1 in.) diam specimen three times for 1 h. (a) ASP 23. (b) ASP 30. (c) ASP 60, cooled in salt bath. Hardening temperatures for the curves are: A, 1180

°C (2155 °F); B, 1150 °C (2100 °F); C, 1100 °C (2010 °F); D, 1050 °C (1920 °F)

Three types of distortion are experienced metallurgically during heat treatment:

- Normal volume change due to phase transformations in the steel
- Variations in volume change in different parts of the tool due to the segregation in the steel
- Distortion due to residual stress caused by machining or nonuniform heating and cooling during heat treatment

Powder metallurgy grades, however, differ significantly from conventionally manufactured high-speed tool steels. Dimensional changes are more uniform in all directions. Because P/M high-speed tool steels are segregation free, variations in dimensional change are smaller. Therefore, the dimensional change that occurs during hardening can be predicted more accurately. Conventionally processed high-speed tool steels go out-of-round in a four-cornered pattern. The extent of distortion during heat treatment depends on the type and degree of segregation. In P/M high-speed tool steels, anisotropy is smaller, and out-of-roundness occurs in a close, circular pattern. Figure 6 shows typical results of measuring 102 mm (4 in.) diam disks after hardening and tempering. With P/M high-speed tool steels, cracking and variation of hardness are minimized because of their fine-grained, uniform structure.

Fig. 6 Out-of-roundness measurements on test disks after hardening and tempering. Test disks machined from 102 mm (4 in.) diam bars. (a) AISI M2. (b) ASP 30

Precautions must be taken to control distortion caused by residual stresses during heat treating. Mechanical stresses from rough machining can be eliminated by stress relieving prior to heat treating and finish machining.

Manufacturing Properties

During manufacturing, as much as 50% of a tool blank can be removed by sawing, turning, drilling, milling, grinding, and other machining operations. Consequently, the machinability and grindability of high-speed steels are important factors that affect alloy selection and the cost of a finished tool. In general, the machinability of the P/M high-speed tool steels in the annealed condition is comparable to and, in many cases, superior to that of conventional high-speed tool steels of similar composition. However, an important advantage of the P/M process is that the machinability of P/M tool steels can be improved by increasing their sulfur contents to much higher than conventional levels without sacrificing toughness or cutting performance. As indicated in Table 1, several P/M high-speed tool steels are available that contain as much as 0.30% S. Depending on specific conditions, the highly resulfurized P/M tool steels can offer as much as a 30% improvement in machinability over P/M tool steels with lower sulfur levels or conventional high-speed tool steels of similar composition.

The grindability of P/M high-speed steels is also superior to that of conventional high-speed steel of the same composition because of the small size and uniform distribution of carbides in P/M steels, regardless of bar size. The

relative grindability of several conventional and P/M high-speed tool steels is illustrated in Fig. 7. The grinding ratio, or volume of metal removed to the volume of wheel worn, is clearly superior for the P/M tool steels, particularly those with high sulfur contents. As expected, the grinding ratios generally decrease for both the conventional and P/M tool steels as their alloy and carbon contents increase. The machining and grinding practices recommended for P/M high-speed steels are given in the article "Machining of P/M Tool Steels" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fig. 7 Relative grindability of CPM and conventional high-speed tool steels. The CPM grades M2S and M3S-2 contain 0.25 to 0.30% S. Source: Crucible Materials Corporation

Cutting Tool Properties

The cutting performance of high-speed steels is primarily determined by their resistance to wear, by their resistance to tempering at operating temperatures (hot hardness), and by their toughness (Ref 6). Wear resistance is generally a function of hardness and of the type, volume, and shape of the primary carbides present in the tool. In this respect, the higher hardness attainable with P/M high-speed tool steels, along with the greater amount of alloy carbides that can be included in these steels, constitutes a significant advantage over conventional high-speed steels. Temper resistance, or hot hardness, is largely determined by the composition and growth of the secondary hardening carbides and is promoted by vanadium, molybdenum, and cobalt; these elements can be used in larger amounts in P/M high-speed steels than in conventional steels without degrading properties. Toughness of the high-speed steels is determined by the state of tempering of the matrix and the spatial and size distribution of the primary carbides. Here again, the uniform distribution and small size of the carbides in P/M high-speed steels represents an important toughness advantage.

The importance of toughness in high-speed tool steels is illustrated in Fig. 8. A cutting edge may suffer from repeated microchipping. As Fig. 8 shows, the cutting edge of ASP 23 steel displays minimal wear. The cutting edge of conventional M2, however, shows microchipping under the same service conditions. Microchipping blunts the cutting edge, increases stress, and accelerates other wear factors.

Fig. 8 Comparison of cutting edge wear of a conventional high-speed tool steel and a P/M high-speed tool steel. (a) Cutting edge of tool made of conventional AISI M2 material showing severe microchipping. (b) Cutting edge of tool made of P/M-processed ASP 23 material showing no microchipping under the same service conditions. Courtesy of Speedsteel, Inc.

As shown in Fig. 9, toughness and hardness can be controlled by varying the hardening temperature. A low hardening temperature produces good toughness. A higher hardening temperature increases hardness, but lowers toughness.

Fig. 9 Bend test results to determine the toughness of P/M-processed ASP high-speed tool steels. A, ultimate bend strength; B, bend yield strength; C, hardness (HRC). (a) Bend strength of a test bar of ASP 23 steel after hardening and tempering at 560 °C (1040 °F) (three times for 1 h). (b) Bend strength of a test bar of ASP 30 steel after hardening and tempering at 560 °C (1040 °F) (three times for 1 h). (c) Bend strength of a test bar of ASP 60 steel after hardening and tempering at 560 °C (1040 °F) (three times for 1 h). Ultimate bend strength may vary $\pm 10\%$; bend yield strength may vary $\pm 5\%$; hardness values may vary $\pm 1\%$. Source: Speedsteel, Inc.

Figure 10 summarizes the relative toughness, wear resistance, and red (hot) hardness characteristics of several P/M and conventional versions of various AISI high-speed tool steel grades. As Fig. 10 shows, the wear resistance and red hardness of a given grade of P/M high-speed tool steel are equal to those of the conventional versions of the same steel. However, wear resistance and red hardness generally increase with alloy content and are highest with the very highly alloyed grades, such as M4, T15, CPM Rex 45, M62 (CPM Rex 20), and M48 (CPM Rex 76). All of these grades are best produced or can be produced only by P/M methods. The toughness comparison shows that the P/M version of each grade is notably tougher than the conventional version.

Alloy Development

As indicated in Table 1, a number of P/M high-speed steels have been developed that cannot be made by conventional methods because of their high carbon, nitrogen, or alloy contents. Examples of these are CPM Rex 20, CPM Rex 25, CPM Rex 76, and ASP 60. CPM Rex 76 is a cobalt-rich high-speed steel with exceptional hot hardness and wear resistance, along with greatly increased tool life in difficult cutting operations. Its high alloy content (32.5%, compared to 27.8% for T15 and 25% for M42) renders this alloy unforgeable if produced by conventional methods.

CPM Rex 20 and CPM Rex 25 are examples of two high-performance P/M high-speed tool steels that were developed as cobalt-free equivalents of M42 or T15 (Ref 19). The latter two grades contain 8 and 5% Co, respectively, and are used in the machining of those difficult-to-machine super-alloys and titanium alloys used by the aircraft industry. Cobalt increases the solidus temperature in high-speed tool steels, thus permitting the use of higher austenitizing temperatures to achieve greater solutioning of alloying elements. Cobalt also enhances the secondary hardening reaction, which results in a 1 to 2 HRC hardness advantage in the fully heat-treated condition. It also enhances hot hardness and temper resistance, thus allowing a tool to retain a sharp cutting edge at higher machining speeds that generate heat. Despite the advantages of adding cobalt, its high cost and occasional lack of availability have necessitated the development of cobalt-free alternatives.

Tables 3 and 4 show the results of temper resistance and hot hardness comparisons of specimens that were heat treated to full hardness. These results show that CPM Rex 20, CPM Rex M42, and conventional M42 are equivalent in both temper resistance and hot hardness. Table 5 compares the Charpy C-notch impact energy and bend fracture strength values obtained for CPM Rex 20, CPM Rex M42, and conventional M42. Both the Charpy C-notch impact energy and the bend fracture strength of CPM Rex 20 are equal to those of CPM Rex M42, but are notably higher than those of conventional

M42. Table 6 gives the results of laboratory lathe tool tests in single-point turning on H13 tool steel and the P/M René 95 super-alloy. The overall performance of CPM Rex 20 is comparable to that of CPM Rex M42.

Table 3 Temper resistance of CPM alloys

Alloy grade	Hardness, HRC				
	As-heat-treated at 1190 °C (2175 °F) + 550 °C (1025 °F) three times/2 h	As-heat-treated +		As-heat-treated +

Applications of P/M High-Speed Tool Steel

Milling. Milling cutters, such as those shown in Fig. 11, are a major application of P/M high-speed tool steels. Stock removal rates can usually be increased by raising the cutting speed and/or feed rate. In general, the feed per cutter tooth is increased in roughing operations, and the cutting speed is increased for finishing operations.

Fig. 11 Typical milling cutters made from P/M high-speed tool steels. Courtesy of Speedsteel Inc.

The performances of conventionally processed and P/M high-speed tool steel end mills in milling Ti-6Al-4V have been evaluated. In these tests, ASP 30 and ASP 60 were compared to M42. The cutting conditions used for this evaluation are given in Fig. 12, which shows tool life versus cutting speed. Both feed per tooth (0.203 mm, or 0.008 in.) and cutting speeds (>45.7 m/min, or 150 sfm) are higher than those used in production practice for machining aircraft parts. At a constant metal removal rate that corresponds to a cutting speed of 53.3 m/min (175 sfm), ASP 60 and ASP 30 lasted 8 times and 4.5 times longer, respectively, than the M42 end mill. Other materials machined by P/M high-speed tool steel milling cutters include tough, hardened steels, such as 4340; austenitic stainless steels, such as AISI type 316; and nickel-base superalloys, such as Nimonic 80.

Cutter, mm (in.)	25 (1) diam end mills
Feed, mm/tooth (in./tooth)	0.203 (0.008)
Radial depth of cut, mm (in.)	6.35 (0.250)
Axial depth of cut, mm (in.)	25.4 (1.000)
Cutting fluid	Soluble oil (1:20)
Tool life end point, mm (in.)	0.5 (0.020) wear

Fig. 12 Results of end mill tests on Ti-6Al-4V. Hardness: 34 HRC

Hole Machining. Reamers, taps, and drills (Fig. 13) are also made from P/M high-speed tool steels. In one application, the tool life of $\frac{1}{4}$ -20 GH3 four-flute plug taps made from CPM Rex M4 and conventional M1, M7, and M42 were compared. The operation consisted of tapping a reamed 5.18 mm (0.204 in.) diam, 12.7 mm (0.500 in.) deep through hole in AISI 52100 steel at 32 to 34 HRC using a speed of 7.9 m/min (26 sfm) and chlorinated tapping oil. Eight to thirteen taps of each grade were tested. The CPM Rex M4 taps had an average tool life of 157 holes tapped before tool failure, compared to 35 holes for M1, 18 holes for M7, and 32 holes for M42. The tool life of the CPM Rex M4 in this application was about five times the life of conventional M42.

Fig. 13 Reamers, taps, and drills made from P/M high-speed tool steels. Courtesy of Crucible Materials Corporation

Broaching tools constitute another major application for P/M high-speed tool steels because tool life is often improved when P/M steels are used to broach difficult-to-cut materials, such as case-hardened steels and superalloys.

One application required broaching six ball tracks that are used in front-wheel-drive automobiles in constant velocity joint hubs made of a case-hardened steel. Figure 14 shows the joint hubs and the broaching tool used. In this broaching application, surface finish and form tolerance requirements are high because subsequent machining is not performed on the ball tracks. In broaching with low-carbon M35 tools with an 18.0 mm (0.709 in.) diameter and a 185.0 mm (7.283 in.) length, the total number of hubs machined per tool was 5600. The M35 tools experienced severe flank wear and developed a large built-up edge, which produced poor surface finishes. With an ASP 30 tool, 20,000 parts were produced.

Fig. 14 Broaching application. (a) Tool made from P/M high-speed tool steel that was used to produce ball

tracks on joint hub. (b) ASP 30 tools produced 20,000 parts compared to 5600 parts by tools made from conventional high-speed tool steel. Courtesy of Speedsteel Inc.

Large broaching tools, such as those shown in Fig. 15, are also being made from P/M high-speed tool steels, such as CPM M3 and M4, to upgrade the broach material and its performance. In general, large rounds for broaches are not available in conventional high-speed tool steels in sizes above about 254 mm (10 in.), but the larger sizes are available in P/M high-speed tool steels. One application for these tools is the broaching of involute splines in bores of truck transmission gear blanks. Bores up to 305 mm (12 in.) in diameter and 1380 mm ($54\frac{1}{4}$ in.) in length have been cut using such tools.

Fig. 15 Large broaching tool made from P/M high-speed tool steel that was used for broaching involute splines in bores of truck transmission gear blanks. Courtesy of Crucible Materials Corporation

Gear Manufacturing. Gear hobs (Fig. 16) made from P/M high-speed tool steels can also provide substantial cost reductions by increasing machining rates. One application called for the hobbing of rear axle gears for heavy-duty trucks and tractor differentials. Hobs made of conventionally processed AISI M35 (65 HRC) and ASP 30 (67 HRC) were compared. Production results showed that the flank wear land on the hobs made of ASP 30 (0.44 mm, or 0.017 in.) was much less than on hobs made of M35 (0.71 mm, or 0.028 in.). Chipping of the edges was infrequent on the ASP 30 hobs, while the M35 hobs frequently displayed such damage.

Fig. 16 Gear hobs made from P/M high-speed tool steels. Courtesy of Speedsteel Inc.

Sintered Tooling

Figure 17 shows a number of P/M high-speed steel tools made by vacuum sintering cold isostatically pressed or mechanically pressed powders. Due to the higher temperatures used in processing, the primary carbides tend to be larger

in vacuum-sintered, rather than hot isostatically pressed, high-speed steels. However, they are still smaller than in conventional high-speed steels of similar composition. Applications in which fully dense vacuum-sintered high-speed steels are currently in use include screw machine tooling, gear cutting tools, and indexable cutting tool inserts.

Fig. 17 Examples of vacuum-sintered parts manufactured by the FULDENS process. Note the complexity of shapes attainable by this process. (a) Using cold isostatic pressing. (b) Using mechanical pressing

P/M Cold-Work Tool Steels

A number of improved, high-vanadium P/M tool steels designed for high-wear and cold-work applications are commercially available. The chemical compositions of four representative P/M cold-work grades are given in Table 1. As with P/M high-speed tool steels, the more uniform microstructure of the P/M cold-work steels yields better toughness. This is very important in cold-work tooling because it allows higher hardnesses to be used with associated improvements in yield strength and wear resistance. Further, the use of higher vanadium contents in P/M cold-work tool steels than is practical in conventional cold-work tool steels has made for substantial improvements in wear resistance.

Both CPM 9V and CPM 10V are examples of two P/M cold-work tool steels with outstanding wear resistance and toughness (Ref 1). CPM 9V is capable of being heat treated to 58 to 60 HRC using austenitizing temperatures at or above 1149 °C (2100 °F). However, much better toughness is obtained in the hardness range of 46 to 55 HRC using austenitizing temperatures ranging from 1038 to 1121 °C (1900 to 2050 °F). The impact toughness and wear resistance values of CPM 9V, compared to those of a number of conventional and P/M hot- and cold-work tool steels, are shown in Fig. 18 and 19, respectively. In Fig. 19, the wear resistance of CPM 9V at 53 to 55 HRC, which is the maximum hardness level recommended for good toughness, is clearly superior to that of conventional D2 (62 HRC) and CPM M4 (64 HRC).

Fig. 18 Charpy C-notch impact properties of CPM 9V and other P/M and conventional tool steels at indicated hardnesses for cold-work applications

Fig. 19 Wear resistance of CPM 9V and other P/M and conventional tool steels at indicated hardnesses

CPM 10V is favored over CPM 9V in cold-work applications where greater hardness, higher compressive strength, or better wear resistance is required. In practice, CPM 10V has proved to be more wear resistant than any commercially available high-alloy tool steel, including the most highly alloyed high-speed tool steels. The outstanding wear resistance properties of CPM 10V are illustrated in Fig. 20, which shows its laboratory wear test data compared to data for conventional D2, M2, and for CPM M4 at the maximum hardness levels typically used with these materials in cold-work tooling. Also included are wear data for D7, A7, and CPM T15. Although hardness has a major effect on wear resistance, its importance in this comparison is overshadowed by the very high vanadium carbide content of CPM 10V.

Fig. 20 Wear resistance of CPM 10V and other P/M and conventional tool steels at indicated hardnesses

Figure 21 shows impact toughness data for CPM 10V compared to D2, M2, conventional M4, and CPM M4 at the same hardness levels used to generate the wear test data in Fig. 20. These results, confirmed by actual field experience, indicate that CPM 10V exhibits toughness comparable to that of conventional D2 and M4.

Fig. 21 Charpy C-notch impact properties of CPM 10V and other P/M and conventional tool steels at indicated hardnesses

Typical applications for CPM 10V include punches and dies for cold-forming and stamping operations, powder metal compaction tooling, roll-forming rolls, wood-working tools, wear parts, and so on. CPM 10V should also be considered as a cost-effective replacement for tungsten carbide and the Ferro-Tic steel-bonded carbides, particularly where these materials are prone to chipping and breakage or where the cost of these materials is prohibitive. Some examples of tooling and wear part applications where CPM 10V has demonstrated its cost effectiveness follow.

Figure 22 shows a typical high-production-rate, progressive stamping die application in which CPM 10V punches were compared to D2 and CPM Rex M4. The material being stamped was a 0.381 mm (0.015 in.) thick copper-beryllium strip. In one operation, D2 piercing punches at 60 to 62 HRC averaged 75,000 parts before losing size; CPM Rex M4 at 64 HRC showed some signs of wear after 200,000 parts; and CPM 10V showed no wear after 400,000 parts and ultimately produced over 1,500,000 parts. In a coining operation in the same progressive die, CPM 10V was compared to D2 to produce a sharp radius bend indentation. D2 at 60 to 62 HRC required regrinding after 50,000 to 60,000 parts because of rounding of the punch nose radius, while the CPM 10V punch showed no signs of wear after 200,000 parts.

Fig. 22 CPM 10V punch and copper-beryllium blank used in a progressive stamping operation. Courtesy of Crucible Materials Corporation

Figure 23 shows a unique wear part application in which CPM 10V was selected both for its high wear resistance and its ability to be manufactured economically into the component shown. This part is an automotive push-rod assembly for diesel engines. CPM 10V was selected to eliminate a localized wear problem on the ball ends. Manufacturing of the balls requires cold or warm upsetting of 6.35 mm (0.250 in.) diam slugs cut from coil stock to form approximately 9.53 mm (0.375 in.) diam balls that are subsequently rough ground, drilled, heat treated, finish ground, and resistance welded to the push-rod stems. This part could not be produced economically in carbide or other pressed and sintered materials.

Fig. 23 Automotive push-rod assembly with wear-resistant spherical CPM 10V tips. Courtesy of Crucible Materials Corporation

CPM 440V is a high-vanadium, high-chromium tool steel for applications requiring both high wear resistance and good corrosion resistance. The composition of this material (Table 1) is essentially that of T440C martensitic stainless steel to which about 5.75% V and increased carbon have been added to improve wear resistance. The wear resistance and toughness properties of CPM 440V are compared with those of T440C, D2, and CPM 10V in Table 7. Although not as wear resistant as CPM 10V, CPM 440V exhibits outstanding wear resistance characteristics compared to conventional T440C and D2.

Table 7 Comparative properties of CPM 440V, CPM 10V, conventional T440C, and D2 tool steel

Alloy grade	Hardness	Crossed-cylinder wear resistance		Charpy C-notch toughness	
		10 ⁷ MPa	10 ¹⁰ psi	J	ft · lbf
CPM 440V	59	276	40	16.3	12
CPM 440V	56	21.7	16
T440C	56.5	28	4	35.3	26
D2	59	28	4	31.2	23
CPM 10V	60	517	75	35.3	26

P/M Tool Steels

K.E. Pinnow and W. Stasko, Crucible Materials Corporation, Crucible Research Center

P/M Hot-Work Tool Steels

The absence of segregation in P/M tool steels makes them very attractive for hot-work tool and die applications because a frequent cause of premature failure of large die casting dies is thermal fatigue attributed to segregation and heterogeneous microstructures (Ref 20). As an example, H13 shot sleeves used to die cast four-cylinder engine blocks had an average service life of about 27,000 pieces when the starting material had little segregation, compared to about 13,000 pieces for material that showed clearly visible segregation in the starting material (Ref 21). During the past 10 years, efforts have been made to develop premium-quality, low-segregation tool and die steels by improved steelmaking processes such as vacuum degassing and vacuum arc or electroslag remelting.

Powder metallurgy processing offers an alternative method of producing segregation-free hot-work tool steels of both standard and improved compositions and offers near-net shape capability. The compositions of three P/M hot-work tool steels now commercially available are given in Table 1. Two are P/M versions of standard H13 and H19 hot-work tool steels, which, when made by P/M methods, have more uniform properties and equivalent or better toughness. The third is a high-vanadium modification of standard H19 with improved toughness and wear resistance.

Figure 24 compares the longitudinal microstructures of P/M H13, standard conventional H13, and premium-quality conventional H13. Both of the conventional H13 alloys show significant microbanding, or alloy segregation, while the P/M H13 material has a homogeneous, segregation-free structure.

Fig. 24 Longitudinal microstructure of (a) standard conventional H13, (b) premium-quality conventional H13, and (c) P/M H13. Vilella's etch. 50×

Results of property determinations made on conventional and P/M H13 to compare their heat treatment response, size change, toughness, tensile strength, and thermal fatigue resistance characteristics are given in Tables 8, 9, 10, and 11. The hardness characteristics across large sections of conventional and P/M H13 after a standard heat treatment [that is, 1010 °C (1850 °F)/1 h, air cool, 593 °C (1100 °F)/2 + 2 h] are given in Table 8. These results show that the attainable hardnesses were the same but that the variation of hardness values across the P/M product was less than that of the conventional material, indicating greater uniformity. Table 9 gives the size change values for these products for the same heat-treated conditions. These results clearly show the isotropic nature of the P/M product.

H13	152 × 406	6 × 16	6000

(a) Preheated at 816 °C (1500 °F); austenitized at 1010 °C (1850 °F) for 1 h, air cooled; tempered at 593 °C (1100 °F) for 2 + 2 h

Table 10 gives the standard Charpy V-notch impact strength and tensile strength values obtained at 21 and 538 °C (70 and 1000 °F). At both test temperatures, the uniform properties of the P/M product are shown by the equal values obtained for longitudinal and transverse specimens and for edge and center locations. Compared to the conventional H13, the P/M product has slightly lower longitudinal toughness but higher transverse toughness. The tension test results show that the P/M and conventional products have equal tensile properties.

Table 11 lists thermal fatigue test results obtained by alternately immersing specimens in molten lead at 621 °C (1150 °F) and water at 93 °C (200 °F) at a frequency of three cycles per minute. The average number of cycles to crack initiation was 50% greater for P/M H13.

Initial field trials of CPM H19V have been encouraging. In one application in which the material was used to punch holes in forged hammer heads at elevated temperatures, it yielded 1700 to 4500 pieces, while conventional H13 averaged only 900 pieces before failure.

Another major benefit of using the P/M process is the ability to produce near-net shape die cavities directly during HIP and thus minimize material input and subsequent machining. Figure 25 is an example of a die produced by ceramic core technology (Ref 22). In this process, a ceramic core material is cast in a reusable aluminum mold to the shape desired in the die cavity to be made. The ceramic core is then assembled with die steel powder in an outer steel container, as shown schematically in Fig. 26. The dies can be made in pairs in a single outer container by using a steel separating plate. After powder loading, the assembly is evacuated, sealed, and hot isostatically pressed to compact the powder to full density and form the powder around the ceramic core. Typical HIP parameters for hot-work die steels are 1149 °C (2100 °F) and 103 MPa (15 ksi). Following HIP, the ceramic cores can be removed by grit blasting and/or chemical leaching. The die is then ready for heat treatment and finish machining operations.

Fig. 25 P/M H19 die produced using prealloyed powder and the ceramic core process. Courtesy of Crucible Materials Corporation

Fig. 26 Schematic diagram of an assembly for producing P/M dies by the ceramic core process

The same process can be used to place cooling water passages within the die. An example is shown in Fig. 27. With the P/M process, these passages can be designed and placed in a manner to make cooling most effective, rather than being restricted by machining limitations. With more effective cooling, die life would be expected to be enhanced.

Fig. 27 P/M H13 die cut open to show cooling passages that were placed in the die using the ceramic core process. Courtesy of Crucible Materials Corporation

Composite near-net shape dies can also be made by the P/M process. A highly alloyed material with high resistance to thermal fatigue or wear can be used in the die cavity while another lower cost or higher strength alloy is used in the remainder of the die. Figure 28 shows a P/M composite that uses Stellite 6 in the die cavity and H13 as the support material.

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Introduction

MARAGING STEELS comprise a special class of high-strength steels that differ from conventional steels in that they are hardened by a metallurgical reaction that does not involve carbon. Instead, these steels are strengthened by the precipitation of intermetallic compounds at temperatures of about 480 °C (900 °F). The term maraging is derived from martensite age hardening and denotes the age hardening of a low-carbon, iron-nickel lath martensite matrix.

Commercial maraging steels are designed to provide specific levels of yield strength from 1030 to 2420 MPa (150 to 350 ksi). Some experimental maraging steels have yield strengths as high as 3450 MPa (500 ksi). These steels typically have very high nickel, cobalt, and molybdenum contents and very low carbon contents. Carbon, in fact, is an impurity in these steels and is kept as low as commercially feasible in order to minimize the formation of titanium carbide (TiC), which can adversely affect strength, ductility, and toughness. Other varieties of maraging steel have been developed for special applications. Maraging steels are commercially produced by various steel companies in the United States and abroad.

The absence of carbon and the use of intermetallic precipitation to achieve hardening produce several unique characteristics that set maraging steels apart from conventional steels. Hardenability is of no concern. The low-carbon martensite formed after annealing is relatively soft--about 30 to 35 HRC. During age hardening, there are only very slight dimensional changes. Therefore, fairly intricate shapes can be machined in the soft condition and then hardened with a minimum of distortion. Weldability is excellent. Fracture toughness is considerably better than that of conventional high-strength steels. This characteristic in particular has led to the use of maraging steels in many demanding applications.

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Physical Metallurgy

The unique characteristics of maraging steels have generated considerable interest, and extensive efforts have been devoted to gaining an understanding of the metallurgy of these steels. Much of this work has been summarized in review papers (Ref 1, 2, and 3) and will not be recapitulated here. A brief description of the metallurgical characteristics of these steels is necessary, however, for an understanding of their behavior.

Maraging steels can be considered highly alloyed low-carbon, iron-nickel lath martensites. These alloys also contain small but significant amounts of titanium. Typical nominal compositions of maraging steels are given in Table 1. The phase transformations in these steels can be explained with the help of the two phase diagrams shown in Fig. 1, which depict the iron-rich end of the Fe-Ni binary system. Figure 1(a) is the metastable diagram plotting the austenite-to-martensite transformation upon cooling and the martensite-to-austenite reversion upon heating. Figure 1(b) is the equilibrium diagram showing that at higher nickel contents the equilibrium phases at low temperatures are austenite and ferrite.

Table 1 Nominal compositions of commercial maraging steels

Grade	Composition, % ^(a)					
	Ni	Mo	Co	Ti	Al	Nb
Standard grades						
18Ni(200)	18	3.3	8.5	0.2	0.1	...
18Ni(250)	18	5.0	8.5	0.4	0.1	...
18Ni(300)	18	5.0	9.0	0.7	0.1	...
18Ni(350)	18	4.2 ^(b)	12.5	1.6	0.1	...
18Ni(Cast)	17	4.6	10.0	0.3	0.1	...
12-5-3(180) ^(c)	12	3	...	0.2	0.3	...
Cobalt-free and low-cobalt bearing grades						
Cobalt-free 18Ni(200)	18.5	3.0	...	0.7	0.1	...
Cobalt-free 18Ni(250)	18.5	3.0	...	1.4	0.1	...

Low-cobalt 18Ni(250)	18.5	2.6	2.0	1.2	0.1	0.1
Cobalt-free 18Ni(300)	18.5	4.0	...	1.85	0.1	...

(a) All grades contain no more than 0.03% C.

(b) Some producers use a combination of 4.8% Mo and 1.4% Ti, nominal.

(c) Contains 5% Cr

Fig. 1 Phase relationships in the iron-nickel system. (a) Metastable. (b) Equilibrium. Source: Ref 4

The metastable diagram indicates the typical behavior of these steels during cooling from the austenitizing or solution annealing temperature. No phase transformations occur until the M_s temperature, the temperature at which martensite starts to transform from austenite, is reached. Even very low cooling of heavy sections produces a fully martensitic structure, so there is no lack of hardenability in these alloys.

Alloying elements alter the M_s temperature significantly, but do not alter the characteristic that transformation is independent of cooling rate. In addition to nickel, the other alloy elements present in maraging steels generally lower the martensite transformation range, with the exception of cobalt, which raises it. One of the roles of cobalt in maraging steels is to raise the M_s temperature so that greater amounts of other alloying elements (that is, titanium and molybdenum, which lower the M_s temperature) can be added while still allowing complete transformation to martensite before the steel cools to room temperature.

Most grades of maraging steel have M_s temperatures of the order of 200 to 300 °C (390 to 570 °F) and are fully martensitic at room temperature. Therefore, retained austenite is generally not a problem in these alloys, and as a result, refrigeration treatments are not needed prior to aging. The martensite is normally a low-carbon, body-centered cubic (bcc) lath martensite containing a high dislocation density but no twinning. This martensite is relatively soft (~ 30 HRC), ductile, and machinable.

The age hardening of maraging steels is produced by heat treating for 3 to 9 h at temperatures of the order of 455 to 510 °C (850 to 950 °F). The metallurgical reactions that take place during such treatment can be explained by using the equilibrium diagram (Fig. 1b).

With prolonged aging, the structure tends to revert to the equilibrium phases--primarily ferrite and austenite. Fortunately, the kinetics of the precipitation reactions that cause hardening are such that considerable age hardening--that is, approximately 20 HRC points (1035 MPa, or 150 ksi)--occurs before the onset of the reversion reactions that produce austenite and ferrite. With long aging times or high temperatures, however, hardness will reach a maximum and then will start to drop, as shown by the data in Fig. 2. Softening in these steels usually results not only from overaging in the usual sense of the term--that is, coarsening of the precipitate particles--but also from austenite reversion. The two processes are interlinked; dissolution of metastable nickel-rich precipitate particles in favor of equilibrium iron-rich precipitates locally enriches the matrix in nickel, which favors austenite formation. Very substantial amounts of austenite (of the order of 50%) can eventually be formed by overaging.

Fig. 2 Hardness of 18Ni(250) maraging steel versus aging time for various aging temperatures. Source: Ref 4

Maraging steels normally contain little or no austenite after standard maraging heat treatments. However, austenite is always present in the heat-affected zones around welds and is sometimes deliberately formed to enhance fabricability or service performance. For example, if maraging steel is to be used in an application where overaging in service is expected, such as in dies for aluminum die castings, it is deliberately overaged slightly before being put into service. This minimizes overaging in service, which often produces tensile stresses at the surface. Extreme overaging to form large amounts of austenite has also been employed as an intermediate treatment to enhance response to cold working or to minimize the effects of thermal gradients during hot working and subsequent storage of extraordinary heavy sections.

Age hardening in maraging steels results primarily from the precipitation of intermetallic compounds. Precipitation takes place preferentially on dislocations and within the lath martensite to produce a fine uniform distribution of coherent particles. The major hardener is molybdenum, which upon aging initially forms Ni_3Mo , with an orthorhombic Cu_3Ti -type structure (Ref 5). The metastable Ni_3Mo phase forms initially because of its better lattice fit with the bcc martensitic matrix. Growth of the Ni_3Mo is restricted by coherency strains, and as such, further aging results in the *in situ* transformation of Ni_3Mo to the equilibrium Fe_2Mo phase, which has a hexagonal C14-type structure (Ref 6). Titanium, which is generally present in maraging steels, promotes additional age hardening through the precipitation of Ni_3Ti , which has a DO_{24} ordered hexagonal structure (Ref 6).

Cobalt does not directly participate in the age-hardening reaction, because this element does not form a precipitate with iron, nickel, molybdenum, or titanium in the 18Ni maraging alloy system. The main contribution of cobalt is to lower the

solubility of molybdenum in the martensitic matrix and thus increase the amount of Ni₃Mo precipitate formed during age hardening. Some hardening also results from a short-range ordering reaction in the matrix that involves cobalt.

Molybdenum also plays the necessary supplemental role of minimizing localized grain-boundary precipitation by lowering the diffusion coefficients of a number of elements in solid solution. Precipitation of these grain-boundary phases severely impairs the toughness of most molybdenum-free ferrous alloys. Work by Schmidt (Ref 7) has shown that discrete particles of austenite are also present on the grain and subgrain boundaries in molybdenum-free 18Ni(300). It has been theorized that the precipitation of these discrete particles of austenite at the grain and subgrain boundaries results in a nickel-depleted zone, which adversely affects the toughness and ductility of the molybdenum-free 18Ni(300) alloy on a localized scale.

The precipitate particles are of a lattice size comparable to that of the martensite matrix and cause little distortion of the matrix. This characteristic, together with the absence of carbon, allows the steel to be age hardened to very high strength levels while minimizing changes in the shape of the part being hardened.

Another important precipitation reaction, which must be avoided if optimum toughness and ductility are to be achieved, can take place when the steel is in the austenitic condition. Maraging steels containing titanium are susceptible to the formation of TiC films at austenite grain boundaries. The solutioning of carbides at temperatures greater than 1150 °C (2100 °F), followed by holding at temperatures of the order of 900 to 1095 °C (1650 to 2000 °F), results in the reprecipitation of titanium carbide in the form of films on austenite grain boundaries. As discussed in the section "Hot Working" in this article, this problem first became evident in hot-worked billets and can be avoided by proper hot-working procedures. Prolonged annealing in this range should also be avoided.

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Commercial Alloys

Table 1 lists the chemical compositions of the more common grades of maraging steel. The nomenclature that has become established for these steels is nominal yield strength (ksi units) in parentheses. Thus, for example, 18Ni(200) steel is normally age hardened to a yield strength of 1380 MPa (200 ksi). The first three steels in Table 1--18Ni(200), 18Ni(250), and 18Ni(300)--are the most widely used and most commonly available grades. The 18Ni(350) grade is an ultrahigh-strength variety made in limited quantities for special applications. Two 18Ni(350) compositions have been produced (see the footnote in Table 1). The 18Ni(Cast) grade was developed specifically as a cast composition.

Special varieties of maraging steels have been developed, including stainless grades, other cast grades, grades of other strength levels, a cobalt-free variety for nuclear service, a grade especially suited for heavy sections, and a grade with superior magnetic characteristics. Some of these steels have been made and used commercially, but only in limited amounts for specific applications.

A number of cobalt-free maraging steels and a low-cobalt bearing maraging steel have recently been developed. The driving force for the development of these particular alloys was the cobalt shortage and resultant price escalation of cobalt during the late 1970s and early 1980s. The nominal compositions for these alloys are also listed in Table 1.

The wrought steels in Table 1 are produced in various forms: forgings, plate, sheet, and bar stock are generally available. Most applications use bars or forgings. Thin strip, although it has been produced, is commercially uncommon. Special varieties can be produced in shapes suitable for specific applications.

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Processing

Melting. Most grades of maraging steel are either air melted, then vacuum arc remelted, or vacuum induction melted, then vacuum arc remelted. Premium grades of maraging steels used in critical aircraft and aerospace applications, for which minimum residual element (carbon, manganese, sulfur, and phosphorus) and gas (O₂, N₂, and H₂) contents are required, are triple melted using the air, vacuum induction, and vacuum arc remelting processes.

The primary goals in melting are a clean microstructure, homogeneity, and low levels of deleterious residual elements, particularly sulfur and carbon. The sensitivity of maraging steels to the presence of inclusions is comparable to that of conventional steels of similar strength. Their sensitivity to residual elements, however, is different. Maraging steels show very little sensitivity to elements, such as arsenic, antimony, and phosphorus, that cause temper embrittlement in conventional quenched and tempered steels. As discussed in the section "Surface Treatment" in this article, maraging steels appear to be more resistant to hydrogen embrittlement than low-alloy steels. Carbon and sulfur are the most deleterious impurities in maraging steels because they tend to form brittle carbide, sulfide, carbonitride, and carbosulfide inclusions. These particles crack when the metal is strained, thus initiating fracture and lowering toughness and ductility.

Steels with high titanium and molybdenum contents are prone to microsegregation of these elements during solidification. If the ingot structure is not homogenized during hot working, a banded microstructure with highly anisotropic mechanical properties may persist. The only effective remedy for microsegregation is to adjust the ingot size and hot-working schedule to ensure elimination of the segregation. With the 18Ni(350) grade, ingot size may have to be smaller than normal, and the maximum hot-working temperature should be kept below 1230 °C (2250 °F).

Hot Working. Maraging steels can be hot worked by conventional steel mill techniques, even though allowances must be made for several unique characteristics. Steels with high titanium contents have greater hot strength than conventional steels and require higher hot-working loads or higher working temperatures. Working above about 1260 °C (2300 °F) should be avoided. To maximize their mechanical properties, maraging steels should be hot worked at the lowest temperatures that equipment power limitations permit.

The precipitation of TiC films at austenite grain boundaries must be avoided. This phenomenon first came to light in billets that had been worked at very high temperatures and then allowed to cool slowly through the temperature range of 750 to 1095 °C (1380 to 2000 °F) or to cool with inadvertent thermal arrests in this range. It is essential that long dwell times in this temperature range be avoided after working is completed so that the titanium and carbon remain in solution.

However, one should keep in mind that it is safe to heat into the 750 to 1095 °C (1380 to 2000 °F) range from room temperature because stable carbides will already have precipitated. This temperature range should be avoided only when cooling from temperatures above 1150 °C (2100 °F).

Cold Working. Maraging steels can be cold worked by any conventional technique when in the solution-annealed (unaged or as-transformed) condition. They have very low work-hardening rates and can be subjected to very heavy reductions (>50%) with only slight accompanying gains in hardness.

In maraging steels, both the strain-hardening exponent and tensile elongation are relatively low. Thus, cold-forming operations that depend on uniform tensile strain before necking (such as deep drawing) are generally limited to mild degrees of deformation. Uniform elongation can be significantly improved by overaging, which produces substantial amounts of austenite. This austenite is metastable and transforms to martensite during cold working, which greatly increases uniform elongation and deep-drawing capabilities.

Heavily cold worked structures can be softened by austenitizing or solution annealing at temperatures of about 815 °C (1500 °F). Cold-worked pieces can be directly age hardened, in which case the total strength includes the increase in strength produced by cold working plus that produced by precipitation hardening. Large amounts of prior cold work decrease toughness after direct aging, and considerable anisotropy in elastic modulus and in toughness may be present in unidirectionally worked structures.

Machining. Maraging steels can be machined by any conventional technique when in the solution-annealed or age-hardened condition. Machinability is generally as good as or better than that of conventional steels of the same hardness. Rigid equipment and firm tool supports are necessary. Tools should be flooded with cutting fluids free of lead, sulfur, and other low-melting components, because residues of these elements may cause surface embrittlement during subsequent heat treatment. The new generation of ceramic tooling provides superior cutting speeds and tool life when working with 18Ni maraging steels.

Heat Treating. The properties of conventionally heat treated maraging steels are given in Table 2 and the mechanical properties of 18Ni(250), cobalt-free 18Ni(250), and low-cobalt bearing 18Ni(250) are compared in Table 3. Maraging steels are usually solution annealed (austenitized) 1 h for each 25 mm (1 in.) of section size. It may be necessary to heat treat sheet products in dry hydrogen or dissociated ammonia to minimize surface damage. The cooling rate after annealing has a minimal effect on microstructure or properties. It is essential, however, to cool the steel completely to room temperature before aging. If this is not done, the steel may contain untransformed austenite and may be much softer than expected.

Table 2 Heat treatments and typical mechanical properties of standard 18Ni maraging steels

Grade	Heat treatment ^(a)	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Reduction in area, %	Fracture toughness	
		MPa	ksi	MPa	ksi			MPa \sqrt{m}	ksi \sqrt{in}
18Ni(200)	A	1500	218	1400	203	10	60	155-240	140-220
18Ni(250)	A	1800	260	1700	247	8	55	120	110
18Ni(300)	A	2050	297	2000	290	7	40	80	73
18Ni(350)	B	2450	355	2400	348	6	25	35-50	32-45
18Ni(Cast)	C	1750	255	1650	240	8	35	105	95

(a) Treatment A: solution treat 1 h at 820 °C (1500 °F), then age 3 h at 480 °C (900 °F). Treatment B: solution treat 1 h at 820 °C (1500 °F), then age 12 h at 480 °C (900 °F). Treatment C: anneal 1 h at 1150 °C (2100 °F), age 1 h at 595 °C (1100 °F), solution treat 1 h at 820 °C (1500 °F) and age 3 h at 480 °C (900 °F)

Table 3 Comparison of the longitudinal, room-temperature mechanical properties of standard, cobalt-free, and low cobalt-bearing 18Ni(250) maraging steels

Heat treatment: solution heat 1 h at 815 °C (1500 °F), then age 5 h at 480 °C (900 °F). Testing was conducted on 63.5 × 88.9 mm (2.5 × 3.5 in.) billets produced from 200 mm (8 in.) diam vacuum induction melted/vacuum arc remelted ingots.

Grade	Ultimate tensile strength		0.2% offset yield strength		Elongation in 25 mm (1 in.), %	Reduction in area, %	Charpy V-notch impact toughness ^(a)		Plane-strain fracture toughness ^(a)	
	MPa	ksi	MPa	ksi			J	ft · lbf	MPa \sqrt{m}	ksi \sqrt{in}
18Ni(250)	1870	271	1825	265	12	64.5	37	27	138	125
Cobalt-free 18Ni(250)	1895	275	1825	265	11.5	58.5	34	25	127	115
Low-cobalt 18Ni(250)	1835	266	1780	258	11	63.5	43	32	149	135

(a) Longitudinal-short transverse orientation tested (L-S orientation)

Aging is normally done at 480 °C (900 °F) for 3 to 6 h. For certain applications (such as die casting dies), aging at about 530 °C (985 °F) is employed. Figure 2 shows hardness versus aging time for 18Ni(250). Hardening is initially very rapid; several minutes at temperature will cause a substantial boost in strength in all grades of maraging steel. With very long times at temperature, hardness begins to drop due to coarsening of the precipitate particles and reversion of the martensite matrix to austenite. Austenite generally starts to form as rather small particles at both prior austenite boundaries and lath-martensite boundaries.

Thermal cycling of maraging steels between the M_f temperature (temperature at which martensite formation finishes during cooling) and a temperature considerably in excess of the solution-heating temperature can be used to refine the grain structure of coarse-grain maraging steels. For example, Saul, Roberson, and Adair (Ref 8) were able to refine an ASTM grain size of -1/1 to an ASTM grain size of 6/7 in 18Ni(300) following three thermal cycles between room temperature and 1025 °C (1880 °F). The shear strains produced by the diffusionless shear transformations of martensite to austenite and of austenite to martensite provide the driving force for recrystallization during these thermal cycles. One should recall that grain sizes finer than ASTM 6/7 cannot be achieved by this process and that the process becomes less effective as the starting grain size becomes finer.

The standard aging treatments listed in Table 2 produce contraction in length of 0.04% in 18Ni(200), 0.06% in 18Ni(250), and 0.08% in both 18Ni(300) and 18Ni(350). These very small dimensional changes during aging allow many maraging steel components to be finish machined in the annealed condition, then hardened. When precise dimensions must be held, an allowance for contraction can be made.

Much effort has been devoted to examining the properties of overaged maraging steels. The general belief is that a microstructure containing coarse precipitate particles and finely distributed austenite particles should have good resistance to both fracture and stress-corrosion cracking. In many instances, this has been found to be so, and very impressive improvements in plane-strain fracture toughness, K_{Ic} , or threshold stress intensity for stress-corrosion cracking, K_{Isc} , have been achieved with only modest reductions in yield strength. Unfortunately, however, there appears to be more heat-to-heat variability when overaging heat treatments are used. This variability is the result of a greater sensitivity of austenite formation to minor changes in composition and processing. Even the most homogeneous-looking structures contain minor alloy segregation that is manifested in the form of alloy-rich and alloy-lean bands. The alloy-rich bands tend to overage more rapidly than their alloy-lean counterparts. It is therefore difficult to recommend specific overaging heat treatments that will produce consistent mechanical properties. Generally, if a specific yield strength is required, it is better to use a maraging steel in which the required strength can be produced by conventional aging than to use an overaged steel of higher strength.

Surface Treatment. Grit blasting is the most efficient technique for removing oxide films formed by heat treatment. Maraging steels can be chemically cleaned by pickling in sulfuric acid or by duplex pickling in hydrochloric acid and then in nitric acid plus hydrofluoric acid. As with conventional steels, care must be taken to avoid over-pickling. The sodium hydride cleaning of maraging steels should be avoided to minimize problems with crack formation. Grease and oils can be removed by cleaning in trichloroethane-type solutions.

Maraging steels can be nickel plated in chloride baths provided that proper surface-activation steps are followed. Heavy chromium deposits can be plated on top of nickel electrodeposits. Maraging steels are less susceptible to hydrogen embrittlement during plating than conventional quenched and tempered steels of comparable hardness. They are not immune to hydrogen, however, and baking after plating is recommended. Baking should be done at temperatures of about 150 to 205 °C (300 to 400 °F) for periods of 3 to 10 h, depending on size and baking temperature. Baking cannot be combined with age hardening, because considerable hydrogen remains in the steel after heat treating at the higher temperatures.

Considerable surface hardening can be achieved by nitriding maraging steels in dissociated ammonia. Hardness levels equivalent to 65 to 70 HRC can be achieved at depths of up to 0.15 mm (0.006 in.) after nitriding for 24 to 48 h at 455 °C (850 °F). Nitriding at this temperature allows age hardening to occur during nitriding; therefore, the two processes can be accomplished simultaneously. Salt bath nitriding for 90 min at 540 °C (1000 °F) has been done successfully. Such treatment must be very carefully controlled to avoid excessive overaging. Both the fatigue strength and the wear resistance of maraging steels are improved by nitriding.

Welding. One of the main virtues of maraging steels is their excellent weldability. The extensive research and development work that has been done to optimize weldability is reviewed in Ref 4 and 9; only a brief summary of that work is given here.

Perhaps the characteristic that most enhances the weldability of maraging steels is that their low carbon content produces a soft, ductile martensite on cooling. A weld heat-affected zone in maraging steels can be divided into three regions. The region closest to the fusion line contains coarse martensite produced by solution annealing. Next is a narrow region containing reverted austenite produced by heating into the 595 to 805 °C (1100 to 1480 °F) range. Finally, there is a region where the maximum temperature reached during welding ranges from ambient temperature up to 595 °C (1100 °F); this region contains martensite that has been age hardened by various amounts. As shown in Fig. 3, the heat-affected zone in an as-welded structure is relatively soft. Because the metal in the area immediately surrounding the weld is soft and ductile, residual stresses are low, and the susceptibility to weld cracking is considerably less than in steels hardened by quenching. Subsequent local aging brings the hardness of the weld zone up to that of the base metal; this effect is also shown in Fig. 3. Resolution heat treating is advisable after welding if optimum properties are desired in the heat-affected weld zone.

Fig. 3 Microhardness of a weld heat-affected zone in 18Ni(250) maraging steel. Source: Ref 4

All conventional welding processes have been used for welding maraging steel. Brazing can also be done. Most fabrication thus far, however, has employed inert-gas welding processes; the least work has been done with flux-shielded processes (Ref 4, 9).

Typical compositions of filler wire for welding maraging steels are listed in Table 4. These compositions are very similar to those of the steels with which they are used. After welding, an aging treatment is used to increase the strength of the weld joint. Weld metal strength does not depend significantly on the welding process used to make the joint; in most applications, joint efficiencies exceeding 90% can be achieved.

Table 4 Typical compositions of filler wire for welding 18Ni maraging steels

Base metal grade	Composition of filler wire, % ^(a)				
	Ni	Mo	Co	Ti	Al
18Ni(200)	18	3.5	8	0.25	0.10
18Ni(250)	18	4.5	8	0.50	0.10
18Ni(300)	18	4.5	10	0.80	0.10
18Ni(350)	17	3.7	12.5	1.60	0.15

(a) All grades contain no more than 0.03% C.

The toughness of the heat-affected zone after age hardening usually matches that of the unaffected base metal. The toughness of the weld metal, however, depends on the joining process. Gas tungsten arc welding produces the best toughness, gas metal arc welds have somewhat lower toughness, and the toughness of flux-shielded welds is poorer yet. In general, high-energy processes that produce coarser weld beads will produce weld metal of lower toughness. This is of special concern with submerged arc welding, where low toughness negates the advantage of the high welding speed associated with that process. The general rules that follow are helpful for obtaining the best properties:

- Avoid prolonged dwell times at high temperatures
- Avoid preheat
- Keep interpass temperatures below 120 °C (250 °F)
- Minimize weld energy
- Avoid slow cooling rates
- Keep welds as clean as possible

Powder Metallurgy Products. Maraging steels having yield strengths of about 1585 MPa (230 ksi), combined with reasonable ductility, have been made by sintering elemental powders. Gas-atomized alloy powders that have been canned and extruded show excellent ductility at yield strengths up to 1900 MPa (275 ksi). However, during the atomization and collection of atomized maraging steel powder, care must be taken to minimize contamination of the surface of the powder particles. The presence of oxides or other nonmetallic inclusions on these surfaces can adversely affect the mechanical

properties of parts consolidated from contaminated powder. Powder metallurgy parts made of maraging steel have been commercially produced only in limited quantities.

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Properties of Maraging Steels

Mechanical Properties. Typical tensile properties and fracture toughness values of the conventional grades of maraging steel are listed in Table 2. One of the distinguishing features of maraging steels is superior toughness compared to conventional steels. Figure 4 compares K_{Ic} values for several maraging steels with those of quenched and tempered alloy steels as a function of tensile strength. The toughness of maraging steels is sensitive to purity level, and carbon and sulfur levels in particular should be kept low to obtain optimum fracture toughness.

Fig. 4 Plane-strain fracture toughness of maraging steels compared with fracture toughness of several ultrahigh strength steels as a function of tensile strength. Source: Ref 2

The mechanical properties of 18Ni(250), cobalt-free 18Ni(250), and low-cobalt bearing 18Ni(250) are compared in Table 3. These data show that all three alloys exhibit comparable strength when aged at 480 °C (900 °F) for 5 h. However, these data also show that, in general, the cobalt-free 18Ni(250) material displays reduced localized ductility as measured by the percentage of reduction in area, and reduced plane-strain fracture toughness compared to the standard 18Ni(250) and low-cobalt bearing 18Ni(250) alloys. The reduced ductility and toughness of the cobalt-free 18Ni(250) alloy is related to the absence of cobalt in this material. The lack of cobalt eliminates the previously discussed cobalt/molybdenum interaction and thus necessitates a higher level of titanium, which is a more potent embrittling agent than either cobalt or molybdenum when present at levels significantly in excess of 1.3%.

The effects of temperature on the mechanical properties of maraging steels are illustrated in Fig. 5. Maraging steels can be used for prolonged service at temperatures up to approximately 400 °C (750 °F). Yield and tensile strengths at 400 °C (750 °F) are about 80% of the room-temperature values. Long-time stress-rupture failures can occur at 400 °C (750 °F), but the rupture stresses are fairly high. At temperatures above 400 °C (750 °F), reversion of the martensite matrix to austenite becomes dominant, and long-term load-carrying capacities decay fairly quickly.

Fig. 5 Effect of temperature on the mechanical properties of 18Ni maraging steels. (a) Stress. (b) Ductility. (c) Hardness. Source: Ref 10

At cryogenic temperatures, the strengths of maraging steels increase similarly to those of steels (Fig. 5); K_{Ic} values fall off roughly in a linear fashion with decreasing temperatures.

The fatigue properties of maraging steels are comparable to those of other high-strength steels. Smooth-bar and notched-bar fatigue properties for 18Ni(200), 18Ni(250), and 18Ni(300) grades are summarized in Fig. 6. Fatigue crack growth rates in maraging steels obey the $da/dN = (\Delta K)^m$ relationship commonly observed in steels, and the rates are similar to those of conventional steels. The bulk of the fatigue life in maraging steels is in the crack initiation stage. In general, cracks tend to initiate at noncoherent intermetallic inclusions, which once again suggests that low levels of residual elements and clean melt practices are important in this alloy system. Improved fatigue properties can be obtained by shot peening and by nitriding.

Fig. 6 Rotating-bean fatigue properties of three 18Ni maraging steels. Source: Ref 2

Resistance to Corrosion and Stress Corrosion. Maraging steels have slightly better corrosion resistance than tempered martensitic alloy steels. In industrial and marine atmospheres, the corrosion rates of maraging steels are about half those of conventional steels. In static and flowing seawater, maraging and conventional steels have essentially the same corrosion rates. In saline and acidic solutions, maraging steels show somewhat better corrosion resistance. Their hot oxidation resistance is noticeably better than that of tempered martensitic alloy steels because of the nickel and cobalt contents of these materials. In general, contact with more noble metals should be avoided to minimize the likelihood of galvanic corrosion.

Maraging steels are susceptible to stress-corrosion cracking in most aqueous environments; their resistance to cracking increases significantly at lower yield strengths. Maraging steels have better resistance to stress-corrosion cracking than tempered martensitic steels of comparable strength. Figure 7 compares K_{Isc} values of several high-strength steels. The resistance of maraging steels to stress-corrosion cracking generally parallels fracture toughness. Processing techniques that improve K_{Ic} (such as vacuum melting, proper hot working, and keeping residual impurity levels low) also improve resistance to stress-corrosion cracking. Surface treatments such as painting or shot peening have been successfully used to increase resistance. Cathodic protection can also be used, but must be employed very carefully to avoid hydrogen charging that could initiate cracking. Maraging steels can be used in aqueous environments; however, as with all high-strength steels, proper precautions to avoid stress-corrosion cracking must be taken.

Fig. 7 Threshold stress intensity for stress-corrosion cracking (K_{Isc}) values for maraging steels and other high-strength steels as a function of yield strength. Source: Ref 11

A comparison of the environmentally assisted cracking (EAC) behavior of production scale lots of 18Ni(250), low-cobalt 18Ni(250), and cobalt-free 18Ni(250) is shown in Fig. 8, 9, and 10. The 18Ni(250) and low-cobalt 18Ni(250) materials used for this comparison testing were produced by Carpenter Technology Corporation; the cobalt-free 18Ni(250) was produced by Teledyne Vasco Corporation. The K_{Ic} and K_{Isc} data contained in Fig. 8 and 9 were produced by tests using compact tension specimens. The K_{Isc} testing was conducted on samples mounted in a fiberglass rack that was 45° to the vertical and facing the prevailing southeast wind on a floating pier located in Galveston Bay. All samples were loaded to K_{init} of 66 MPa \sqrt{m} (60 ksi $\sqrt{in.}$), and the test duration was 1000 h. The proof-ring tensile data contained in Fig. 10 is from a test conducted in a stagnant 3.5% NaCl solution using Plexiglas vessels. Figures 8 and 9 show that both the 18Ni(250) and low-cobalt 18Ni(250) alloys display improved K_{Ic} , K_{Isc} , and EAC growth compared to the cobalt-free 18Ni(250) alloy. Based on Fig. 10, the apparent threshold stress levels for 18Ni(250), low-cobalt 18Ni(250), and cobalt-free 18Ni(250) in stagnant 3.5% NaCl are 1035 MPa (150 ksi), 860 MPa (125 ksi), and 515 MPa (75 ksi), respectively.

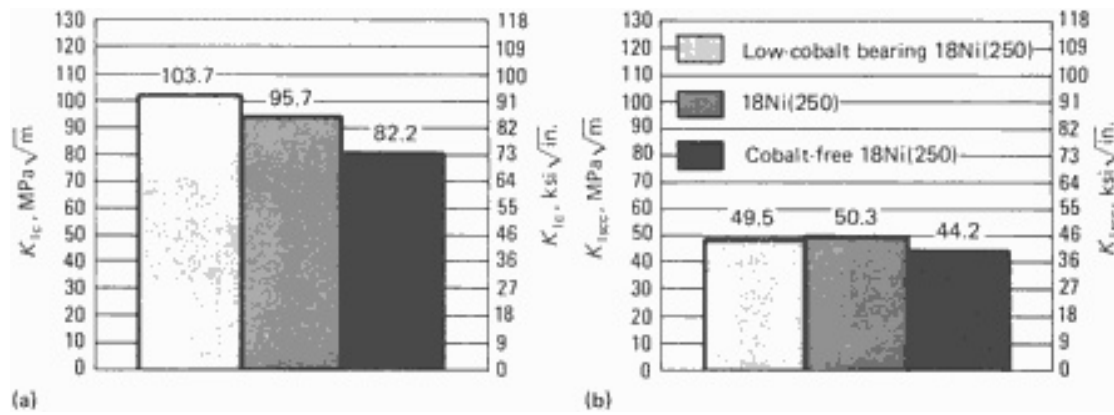

Fig. 8 Bar graphs comparing plane-strain fracture toughness K_{Ic} (a) and K_{Isc} (circumferential-radial specimen orientation) (b) of low-cobalt bearing, standard, and cobalt-free 18Ni(250). K_{Isc} testing was conducted in a marine atmosphere. Heat treatment: 815 °C (1500 °F), 1 h, air-cooled; 480 °C (900 °F), 5 h, air-cooled. Source: Ref 12

Heat treatment: 815 °C (1500 °F), 1 h, air-cooled; 480 °C (900 °F), 5 h, air-cooled. Source: Ref 12

Physical Properties. Table 5 summarizes the physical properties of 18Ni(250) maraging steel. Grade 18Ni(250) is the most widely used and most thoroughly evaluated maraging steel. Consequently, more extensive physical property data are available for this steel than for other maraging steels (Ref 13).

Table 5 Selected physical and mechanical properties of 18Ni(250) maraging steel

Density, g/cm ³ (lb/in. ³)	8.0 (0.289)
Coefficient of thermal expansion, μm/m · K (μin./in. · °F) at 24-284 °C (75-543 °F)	10.1 (5.6)

Maraging Steels

Revised by Kurt Rohrbach and Michael Schmidt, Carpenter Technology Corporation

Applications

Maraging steels have been used in a wide variety of applications, including missile cases, aircraft forgings, structural parts, cannon recoil springs, Belleville springs, bearings, transmission shafts, fan shafts in commercial jet engines,

couplings, hydraulic hoses, bolts, punches, and dies. Maraging steels have been extensively used in two general types of applications:

- Aircraft and aerospace applications, in which the superior mechanical properties and weldability of maraging steels are the most important characteristics
- Tooling applications, in which the excellent mechanical properties and superior fabricability (in particular, the lack of distortion during age hardening) are important

In many applications, even though maraging steels are more expensive than conventional steels in terms of alloy cost, finished parts made of maraging steel are less expensive because of significantly lower fabrication costs. Therefore, it is often economics rather than properties alone that determine the use of maraging steels.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Introduction

POWDER METALLURGY (P/M) in its simplest form consists of compressing metal powders in a shaped die to produce green compacts. These are then sintered, or diffusion bonded, at elevated temperatures in a furnace with a protective

atmosphere. During sintering, the constituents usually do not melt, and the compacts become substantially strengthened by the development of bonds between individual particles.

For a specific metal powder and sintering condition, increased compact density results in improved mechanical properties. The density of sintered compacts may be increased by re-pressing. When re-pressing is performed primarily to increase dimensional accuracy rather than density, it is termed sizing. When re-pressing is intended to change the contour of the surface in contact with the punches, it is termed coining. For example, a sintered blank could be coined so that the surface is indented with small slots or letters and numbers. The re-pressing may be followed by resintering, which relieves the stresses due to cold work and may further strengthen the compact.

Alloy compacts can be formed from mixtures of metal powders that completely or partially diffuse during sintering. Alternatively, each individual particle may be completely prealloyed prior to compaction. The diffusion bonding process may be accelerated by sintering at a temperature at which one of the constituent metals is molten. For metals with relatively high melting points, such as iron or tungsten, a skeleton may be pressed, which is then infiltrated by a molten metal, such as copper or silver, having a melting point lower than that of the skeleton.

Process Capabilities. Theoretical density commonly refers to the density of a pore-free material of defined chemistry and thermomechanical history. For example, the theoretical density of iron or low-carbon steel is about 7.87 g/cm^3 . Adding carbon or oxide inclusions to the solid steel lowers the theoretical density, even though no pores are formed.

By pressing and sintering only, parts are produced at 80 to 93% of theoretical density. By re-pressing, with or without resintering, the materials may be further densified to 85 to 96% of theoretical density. High-temperature sintering will also produce parts at these high densities. The density of pressed parts is limited by the size and shape of the compact. The most common P/M materials for structural parts are iron-copper-carbon, iron-nickel-carbon, and iron-carbon. Parts made from these materials respond to heat treatment with a defined hardenability band. Iron parts that are low in carbon and high in density can be carburized and quenched to form a definite, hard case.

Powder metallurgy parts are frequently competitive with forgings, castings, stampings, numerically controlled machined components, and fabricated assemblies. Within the limitations inherent to the P/M processes (discussed in detail in *Powder Metallurgy Technologies and Applications*, Volume 7 of *ASM Handbook*), parts can be fabricated to final or near-final shape, thereby eliminating or reducing scrap metal, secondary machining, and assembly operations. Although the unit cost of metal powder (about \$0.73/kg, or \$0.33/lb in 1989) is usually higher than that of steel bars, the savings achieved by eliminating fabricating operations and minimizing scrap losses often result in lower total costs for P/M parts. The pressing operation in an intricate set of tooling provides very complex geometry, at production rates of 8 to 60 pieces per minute.

Certain metal products can be produced only by powder metallurgy; among these products are materials whose porosity (number, distribution, and size of pores) is controlled. Two examples of controlled-porosity materials are filter elements and self-lubricating bearings. The porosity in a self-lubricating bearing is filled with oil, which lubricates the bearing/shaft interface as the temperature starts to rise.

Successful production by powder metallurgy depends on the proper selection and control of process variables:

- Powder characteristics
- Powder preparation
- Type of compacting press
- Design of compacting tools and dies
- Type of sintering furnace
- Composition of the sintering atmosphere
- Choice of production cycle, including sintering time and temperature
- Secondary operations and heat treatment

Metal Powder Characteristics and Control

The size and shape of powder particles have important effects on pressing and sintering characteristics, but the performance of each type of powder can be determined only empirically. The size and shape of iron powder particles are largely determined by the process used in producing the powder. Powder particles representative of the principal production processes are shown in Fig. 1.

Fig. 1 Scanning electron micrographs of various iron powder particles. (a) Water-atomized and annealed iron powder (Ancorsteel 1000). Arrows indicate small fines that were agglomerated into larger particles. 190 \times (b) Iron powder (Atomet 28). Arrows indicate porosity in the spongy regions. 750 \times . (c) Hydrogen-reduced sponge iron (Pyron 100). Arrows indicate pores opening into the spongy interior. 1000 \times . (d) Carbon-reduced iron ore (MH-100). Arrows indicate one particle with coarse internal porosity. 750 \times

To ensure uniformity in the handling and press performance of powders from batch to batch and in the strength of the compacts formed from them, laboratory tests are usually made on samples of powder from each batch. The results of quality control tests can be applied only to samples of the same basic composition made by the same method. This limitation is evident in Fig. 2, which shows typical compressibility values for three types of iron powders, atomized, prealloyed 4600V, and hydrogen-reduced sponge iron.

(b)

Fig. 2 Effects of compacting pressure on density and mechanical properties. (a) Density versus compacting pressure for three types of iron powders. (b) Ultimate tensile strength versus density for FC-0208 (Fe-2%Cu-0.8%C).

Test procedures are commonly specified for sampling and for the determination of particle size distribution, flow rate, apparent density, weight loss in hydrogen, compressibility, green strength, sintering characteristics, and chemical composition. A cross-index of standards for testing metal powders and ferrous P/M products is given in Table 1.

Table 1 Test methods applicable to powder metallurgy

Methods applicable to metal powders	Designation		
	ASTM	MPIF	ISO
Compressibility of metal powders	B 331
Compression testing of metallic materials at room temperature	E 9
Density, apparent, of metal powders	B 212	4	3923/1

Sampling. Metal powders in containers are usually sampled by turning a specially designed auger-type sampler called a sampling thief vertically to the bottom of the container and removing the column of powder. (A straight, hollow tube does not provide a representative sample). One or more of these samples are taken from each drum of powder, the number of samples depending on the drum size. Samples taken in this manner are combined and reduced to the required size by means of a so-called sample splitter, or by rolling, coning, and quartering.

Particle Size Distribution. A complete screen analysis of the particle size distribution is determined by placing a 100 g (3.5 oz) sample of powder in the top screen of a "nest" of standard sieves having successively smaller openings, usually

80, 100, 140, 200, and 325 mesh. The assembly is shaken mechanically for 15 min. The powder that is retained on each mesh size and the powder that passes through the finest sieve are reported as weight percentages of the sample.

The powder passing 325-mesh can be further analyzed for its subsieve particle size distribution by use of an optical or electron microscope or by the scattering of laser light.

Flow Time. The standard (Hall) flowmeter for metal powders is a funnel-shape apparatus having a calibrated orifice. The time required for 50 g (1.75 oz) powder to flow unaided through the orifice is reported as the flow time of the powder.

Apparent Density. The Hall flowmeter is also used to determine the apparent density of free-flowing powders. For nonflowing powders, use is made of a baffled rectangular tower fed by a funnel having a large orifice (Scott volumeter). The Arnold meter measures apparent density and approximates the value that is found in actual press operation. All three instruments serve to supply a controlled flow of powder into a cup of known volume. The content of the full cup is weighed, and the apparent density is reported as g/cm^3 .

Oxide Content. A fairly accurate indication of the hydrogen-reducible oxide content of metal powders can be obtained by reducing a weighed sample of the powder in hydrogen under standard time-temperature conditions. The sample must be cooled to room temperature in an atmosphere of dry hydrogen. Loss in weight caused by reduction of the oxides present is expressed as a percentage of the initial sample weight. Direct determination of oxygen may also be used to estimate the oxide content of the powder.

Compressibility is the density to which a powder can be pressed at a given pressure. Alternatively, it can be expressed as the pressure required to attain a given density (see Fig. 2).

Green Strength. The strength of a green (unsintered) compact is usually determined by pressing a given weight of powder to a specified density in the shape of a rectangular bar of standard size. This test bar is supported at both ends as a simple beam and loaded transversely to fracture. The modulus of rupture is reported as the green strength of the powder.

Sintering Characteristics. A weighed quantity of a powder is compacted under controlled conditions in a die of known dimensions. After sintering under controlled conditions, dimensional measurements are again taken. The difference in size is usually given as a percentage of the die dimension. Finally, the specimen is tested for mechanical properties. Sintering characteristics are generally reported in terms of dimensional changes, final density, and mechanical properties. The test is usually done by comparing the dimensional change or strength to a standard or reference bar processed at the same time.

Chemical Composition. In addition to the above tests, routine chemical analyses usually are run on all powders to determine the amount of alloying elements and impurities that might adversely affect the final product.

Ferrous Powder Metallurgy Materials

Powder Preparation

Powders are mixed or blended before use. This is done to obtain specific properties (for example, dimensional change or strength) in the finished product. Mixing or blending must be carefully controlled. Also, it is important to use equipment that mixes rapidly and produces a uniform distribution of the powders in the desired proportions in minimum time.

Excessive blending, especially in an overloaded blender, may work harden the powder, making it less compressible and thus more difficult to compact. The cascading of powder inside the blender will gradually round the edges of the particles, changing their shape and raising apparent density. As a result, the powder will exhibit different molding characteristics.

The double-cone blender is probably the most extensively used of the various types available. The final operation before compaction is to mix the powders with a lubricant, such as synthetic wax or stearic acid. The lubricant not only minimizes die friction and wear, but also reduces interparticle friction, allowing the particles to pack more closely and resulting in

higher density for the lower range of molding pressure. Because of a hydraulic effect, densities above 7.0 g/cm³ require less lubricant.

Small percentages of alloying additives such as graphite, copper, or nickel powders, if required, are also introduced during final mixing. Powder manufacturers are beginning to provide bonded mixes in which $\frac{1}{8}$ % of a polymer attaches the additives to the iron powder. This prevents segregation, increases flow rate, and decreases dimensional variation among parts.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Powder Compacting

Compacting powder serves several important functions: The powder is consolidated into the desired shape--a compact that must be strong enough to withstand subsequent processing; compacting controls the amount and type of porosity of the finished product; and compacting is largely responsible for the final dimensions of the part, subject to dimensional changes during sintering.

Of the numerous compacting methods, closed-die pressure compacting and room temperature is the method that is most commonly used in the production of ferrous powder metallurgy parts. A detailed discussion of the various compacting methods, their capabilities and limitations, and the equipment required by each method may be found in *Powder Metallurgy Technologies and Applications*, Volume 7 of *ASM Handbook* or in Ref 1 and 2.

Green strength is an important property of a green compact; the compact must be strong enough to avoid damage during ejection from the die and during normal handling between compacting and sintering. The green strength of a compact is affected by the type and composition of the powder, the distribution of powder particles with respect to both size and shape, the quantity and type of lubricant added to the powder, the configuration of the die, and the compacting pressure. If other compacting conditions are held constant, the green strength of powder metallurgy compacts will vary directly with compacting pressure. Also, as shown in Fig. 2, green density of compacts increases with compacting pressure. Green density is indicative of the density that can be expected after sintering.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Sintering

Sintering is the process by which a compact of metal powder is bonded by heating at a temperature below the melting point, or liquidus, of the major constituent. In iron-graphite mixes, no melting occurs during sintering. In the commonly Fe-2Cu-0.8C mixes, the copper melts and diffuses into the iron. For an M-2 tool steel, sintering is done above the solidus temperature with 15 to 20% permanent liquid phase.

Densification does not occur in most commercially produced P/M parts. Sintering conditions and alloys are adjusted so that the final part is very close to the die size that molded it.

Sometimes a liquid phase forms and assists in sintering. This is true for the Fe-2Cu-0.8C mixtures noted above. The Fe-0.45P and Fe-0.8P contain Fe₃P, which melts as a eutectic 1048 °C (1918 °F) and forms a transient liquid phase. An example of a permanent liquid phase is the infiltration of iron with copper in which 10 to 20 wt% copper remains as a liquid inside the iron skeleton, prior to cooling. The iron-copper infiltrated parts do not shrink. The permanent liquid in the M-2 tool steel causes about 6% linear shrinkage and near-full densification.

The process operating in sintering to form necks or bonds between the particles include surface, volume, and grain-boundary diffusion. In the initial stages of sintering, the atoms move over the surfaces of the particles toward the small radius of curvature regions, where the particles contact each other. During sintering, the compact initially shows increases in strength, thermal conductivity, and electrical conductivity. The particle contacts formed in pressing become larger. Later, the strength increases. Finally, toughness, ductility, and density increase with longer sintering time. The structure changes from an interlocked aggregate of powders to what may be thought of as a solid material containing small pores of various sizes and shapes. At longer sintering times, the densification results in the isolation of the pores. They are no longer connected to the surface. To obtain nearly fully density, it is necessary to sinter at temperatures approaching the melting point of the powder. A more detailed sintering theory is found in "Consolidation Principles and Process Modeling" in *Powder Metal Technologies and Applications*, Volume 7 of *ASM Handbook*, p 309-321.

Sintering Techniques. The equipment and techniques used in sintering are diversified; there must be a means of heating the parts in a suitable protective atmosphere and a means of controlling the process variables. Heating and cooling rates, time and temperature of sintering, and composition of the atmosphere are the most critical variables. The dimensions of the finished parts can be affected by the sintering conditions, as well as by the compacting process and the properties of the powder itself. In the sintering of ferrous metals, the atmosphere serves a dual purpose: It both protects the metal from oxidation and helps to control the carbon content of the parts, especially the carbon content at the surface. Commercial ferrous powders, including prealloyed steel powders, generally contain very little carbon. The carbon content of the finished part is regulated by the amount of graphite mixed into the powder and the carbon potential of the sintering atmosphere. Particularly in alloy steels, the rate of cooling from the sintering temperature can determine which microconstituents are formed as a result of austenite decomposition, but the rate of cooling generally is slow enough to produce ferritic or pearlitic microstructures.

Sintering Equipment. Most iron parts are sintered in mesh belt conveyor furnaces at 1105 to 1120 °C (2020 to 2050 °F) in a mixture of nitrogen and 10% dissociated ammonia. The parts pass through a delubrication zone at 760 to 870 °C (1400 to 1600 °F) and then spend about 15 to 25 min at the high-heat temperature. These furnaces produce 90 to 360 kg/h (200 to 800 lb/h) of parts. They have been improved by the addition of preheat zones that heat rapidly using gas flames to provide an oxidizing environment, which prevents blistering and sooting of parts. Other furnaces have forced atmosphere gas recirculating coolers at the discharge end. These can give finer pearlite spacing or can even form some martensite or bainite, for increased strength.

For higher temperatures and improved toughness, parts are now being sintered in large-scale walking beam furnaces at 1230 to 1315 °C (2250 to 2400 °F). Yield can be up to 900 kg/h (2000 lb/h), with good dimensional control and decreased spread in mechanical properties, as well as increases in the mean properties. Mesh belts of SiC were introduced in 1989, allowing sintering at 1315 °C (2400 °F) and higher.

Stainless steel, silicon iron, and tool steels are usually sintered in vacuum furnaces. The lubricant is generally removed first in a separate furnace. Such delubrication furnaces have been linked to vacuum furnaces in such a way that trays of parts are automatically delubricated, transferred for sintering, and then transferred for gas pressure quenching. Rapid quenching in gas prevents the pickup of nitrogen in 316 stainless steel and promotes better corrosion resistance. Some furnaces are capable of 1315 to 1540 °C (2400 to 2800 °F). Furnaces with sweep gas systems can remove the binder in the vacuum furnace without the use of a separate atmosphere furnace.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Secondary Operations

In many applications, a P/M part that is made by compacting and sintering meets every performance requirements. In other instances, however, the functional requirements (mechanical properties, surface finish, and/or dimensional tolerances) for a part exceed the capabilities of compacted and sintered parts, and one or more secondary operations are required. Some of the common secondary operations are:

- *Sizing*: To tighten dimensional tolerances, usually in the radial direction, relative to the direction of compacting pressure
- *Coining*: To change axial dimensions and tolerances
- *Machining*: To obtain shapes that cannot be compacted, such as by tapping holes or cutting undercut grooves
- *Forming*: To change the shape of the part; can be done hot or cold
- *Re-pressing*: To reduce porosity and increase strength and ductility; may be accompanied by resintering
- *Infiltration*: To increase strength and decrease porosity
- *Heat treating*: To increase hardness and strength
- *Joining*: By sinter bonding, staking, brazing, infiltrating, or welding
- *Finishing*: Includes deburring, polishing, impregnating, and plating

When the application of a P/M part requires high levels of strength, toughness, or hardness, the mechanical properties can be improved or modified by infiltration, heat treatment, or a secondary mechanical forming operation such as cold (room-temperature) re-pressing or powder forging (hot forming). The effect of these secondary processes on P/M mechanical properties is discussed in later sections of this article.

Designation of P/M Materials

Powder metallurgy materials are customarily designated by the specifications or standards to which they are made, such as those listed in Tables 2 and 3. Comparable standards are published by ASTM, SAE, and MPIF (Metal Powder Industries Federation).

Table 2 Compositions of ferrous P/M structural materials

Description	Designation ^(a)			MPIF composition limits and ranges, % ^(b)

The MPIF designations for ferrous P/M materials, described in detail in Ref 3, include a prefix of one or more letters (the first of which is F to indicate an iron-base material), four numerals, and a suffix. The second letter in the prefix identifies the principal alloying element (if one is specified); the percentage of that element is indicated by the first two digits. The third and fourth digits indicate the amount of carbon in the compacted and sintered part; the code designation 00 indicates less than 0.3%, 05 indicates 0.3 to 0.6%, and 08 indicates 0.6 to 0.9%. The suffix is used to indicate the minimum 0.2% yield strength of as-sintered parts and the minimum ultimate tensile strength of heat-treated materials in units of 1000 psi (6.894 MPa). The letters HT designate heat treated.

Commercially produced iron-base powders often contain controlled amounts of alloying elements other than those specified by any of the designations listed in Table 2. Manganese and molybdenum may be added to improve strength and the response to heat treatment. Sulfur may be added to enhance machinability. Additions of 0.45 to 0.80% P can improve the toughness of the part and reduce magnetic hysteresis losses. These powders are usually identified by the trade name of the producer even though the amounts of alloy additions are small enough that the designations listed in Table 2 could be applied to the powders. Commercially produced iron-base powders usually contain very little carbon because carbon lowers compressibility and the amount of carbon in the finished part is readily controlled by the amount of admixed graphite and the composition of the sintering atmosphere.

Commercially produced stainless steels also contain controlled amounts of alloying elements, particularly chromium and nickel. Table 3 lists the designations and compositions of some typical stainless steel P/M materials.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Mechanical and Physical Properties of Sintered Ferrous P/M Materials

The mechanical and physical properties of compacted and sintered ferrous powder metallurgy materials depend on many factors. Some factors, such as microstructure, chemical composition, and heat treatment, affect the properties of P/M materials just as they affect the properties of wrought or cast steels. However, these factors themselves are affected by conditions unique to the P/M process, such as type of iron powder, whether alloying additions are prealloyed or admixed, type and amount of lubricant added to the powder, variations in the compacting process, and sintering conditions. For example, prealloyed powders generally produce stronger and tougher parts than do powders mixed from elemental metal powders, assuming that the same compacted density is obtained with each powder. The variations in the P/M process, such as compacting pressure and sintering temperature, also affect the properties of P/M materials.

Porosity. The most obvious distinction between the microstructures of wrought and powder metallurgy materials is the porosity often found in powder metallurgy materials. This porosity originates as the spaces between powder particles and persists to some extent through sintering and subsequent secondary operations. The microstructure in Fig. 3 shows an example of a pore in a P/M material.

Fig. 3 Atomized iron powder with 0.3% graphite added to yield 0.1 to 0.2% combined carbon (6.7 g/cm^3). Pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia. White regions are ferrite. Arrows E surround a colony of eutectoid (pearlite). Arrow P points to a pore. 2% nital. 545x

As was shown in Fig. 2, different base irons of the same density or porosity level have widely differing tensile properties. For that reason, a minimum density is no longer a requirement for a P/M material. P/M materials are specified in terms of the guaranteed minimum 0.2% tensile yield strength for as-sintered materials, and the minimum ultimate tensile strength for heat-treated materials. Nonetheless, for a specific base iron powder and degree of sintering, mechanical properties do increase with density. Under the guaranteed minimum property system, the design engineer selects the tensile properties and chemistry he needs, and the parts fabricator chooses the density, base iron, sintering, and heat treatment to provide the properties. Table 4 shows all the guaranteed minimum tensile properties and related typical properties for the P/M materials that have been standardized by the MPIF.

Table 4 Minimum and typical mechanical properties of ferrous P/M materials

Minimum strength values (in ksi) are specified by the suffix of the material designation code in the first column of the table. Typical values are given in the remaining columns.

- (a) The suffix of the material designation codes represent either the minimum yield strength or the minimum ultimate strength in ksi. For example, the minimum yield strength of F-0000-10 is 10 ksi, while the minimum yield strength of F-0000-15 is 15 ksi.
- (b) Unnotched Charpy test.
- (c) Where applicable, the matrix (converted) hardness is also given in the footnotes.
- (d) Fatigue limit for 10^7 cycles from reverse-bending fatigue tests.
- (e) The suffix number represents the minimum yield strength (in ksi) for the material in the as-sintered condition.
- (f) The suffix number for heat-treated (HT) materials represents the minimum ultimate tensile strength in ksi. Tempering temperature for heat-treated materials is 175 °C (350 °F).
- (g) Yield strength and ultimate tensile strength are approximately the same for heat-treated materials.
- (h) Or a matrix (converted) hardness of 58 HRC.

- (i) Or a matrix (converted) hardness of 60 HRC.
- (j) Or a matrix (converted) hardness of 55 HRC.
- (k) Or a matrix (converted) hardness of 57 HRC.
- (l) All data based on single-pass infiltration.
- (m) Codes for the stainless steel designations: N1, nitrogen alloyed, with good strength and low elongation; N2, nitrogen alloyed, with high strength and medium elongation; L, low carbon, with lower strength and highest elongation; HT, martensitic grade, heat treated, and highest strength.

The effects of density on the mechanical properties of heat-treated 2% Ni steel, FN0208, are given in Fig. 4. The effects of density on the mechanical properties of sintered pure iron, F-0000, are shown in Fig. 5.

The apparent hardness of P/M materials is measured with the regular Rockwell hardness tester. The HRC, HRB, and HRF scales measure the resistance to indentation. They average the true hardness of the matrix material and the porosity and show lower readings than the corresponding material at full density. They are effective for quality control when applied to a specified region of the part, and an average of five readings is taken. Table 5 shows some typical Rockwell hardnesses and the precision that may be expected.

Table 5 Precision of Rockwell apparent hardness readings on P/M parts

All laboratories tested identical coupons. If similar but different coupons were to be compared, variability would be increased, and larger differences between respective readings would be expected.

MPIF material designation	Density, g/cm ³	Number of laboratories	Average apparent hardness	Repeatability ^(a) (95% confidence limits)		Reproducibility ^(a) (95% confidence limits)

The abrasion or wear resistance of heat-treated materials is measured by the 100 g Knoop microhardness. Through the use of a microscope, these hardness measurements, made on the solid regions between the pores, show the intrinsic hardness of the steel matrix. The Knoop microhardness may be directly converted to HRC readings using the method described in "Testing and Evaluation of Powder Metallurgy Parts" in *Powder Metal Technologies and Applications*, Volume 7 of *ASM Handbook*. The precision or reproducibility between laboratories of the measurement of microhardness on a 4650 heat-treated P/M steel is 3 HRC points when the laboratories take the average of six readings and use the conversion method noted above. Comparison of Knoop 100 g readings has a reproducibility between laboratories of 48 points, when the average of six readings are compared between laboratories.

In the range of densities normally encountered, the fatigue strength of a ferrous P/M material is approximately 25 to 40% of its tensile strength, regardless of composition. The effect of porosity on several other properties that are generally considered independent of variations in structure is given in Fig. 6 and in Table 6.

Table 6 Effect of density on elastic modulus and Poisson's ratio

Density range, g/cm ³	Elastic modulus		Poisson's ratio
	GPa	10 ⁶ psi	
5.6-6.0	72	10.5	0.18
6.0-6.4	90	13	0.20
6.4-6.8	110	16	0.21
6.8-7.2	130	19	0.23
7.2-7.6	160	23	0.26

Fig. 6 Effect of density on the elastic modulus of sintered irons and steels after sintering to various densities

Composition. Alloying elements are added to ferrous P/M materials for the same reasons they are added to wrought or cast steels: primarily to improve strength and hardenability. The alloying elements most commonly used in ferrous P/M materials are carbon, copper, nickel, and molybdenum. The alloying elements are chosen for easy reduction in hydrogen. The amounts of alloying additions are important to the properties of the material, but so are the forms and sources of the alloying elements, particularly, whether they are added as elemental powders or as prealloyed powders. Elemental additions allow better compressibilities, but prealloying gives greater depth of hardening.

Carbon is the most important alloying element in P/M alloys because it strengthens iron and enables it to be heat treated. The effect of carbon content on the ultimate tensile strength of sintered iron is shown in Fig. 7. This strengthening effect can be traced to an increase in the amount of pearlite in the microstructure. As-sintered hypereutectoid P/M steels may have very low strength because proeutectoid cementite forms at austenite grain boundaries. The brittle cementite between the pores can fracture under relatively low levels of macroscopic stress. Combined carbon contents over 0.8% are not recommended.

Fig. 7 Tensile properties of as-sintered iron-carbon alloys at 6.7 g/cm^3 as a function of carbon content. Source: Ref 3

Iron and prealloyed steel powders are usually made with very low carbon content to maximize their compressibilities; carbon is added to these powders as admixed graphite. The carbon content of the sintered compact is also affected by the composition of the sintering atmosphere. The amount of graphite that is retained in the sintered compact as combined carbon depends on the sintering atmosphere and temperature, the source and type of both the graphite and the metal powder, and the amount and types of oxides in the metal powder. The correct graphite addition is determined empirically for each lot of iron powder.

Copper increases the strength of ferrous P/M materials, as shown in Fig. 8, primarily through solid-solution strengthening. Copper is also thought to accelerate the sintering and homogenizing processes, particularly if elemental copper or a copper-rich master alloy exists in the liquid state during the early stages of sintering. Copper causes atomized iron-base compacts to expand during sintering; thus, additions of copper can be used to compensate for shrinkage in iron-carbon or iron-carbon-nickel alloys (Ref 4). Sponge iron blends with elemental copper do not expand.

Fig. 8 Effect of copper and carbon content on the tensile strength of ferrous P/M materials. Source: Ref 3

Nickel strengthens ferrous P/M alloys by solid-solution strengthening and increases their hardenability. The effect of nickel content on the mechanical properties of P/M nickel steels is given in Fig. 9. The presence of nickel increases shrinkage during sintering; additions of copper help maintain dimensions during sintering. The heterogeneous microstructure with nickel-rich islands (see Fig. 10) decreases notch sensitivity and raises tensile strength and impact resistance of the heat-treated materials. The copper helps dissolve nickel in iron and increases hardenability.

Molybdenum and nickel are the elements most frequently added to iron powders to improve hardenability. The amounts of these elements are relatively small, as in the MPIF designations FL-4605 and FL-4205. These two commonly used prealloyed powders correspond in composition to 46xx and 42xx wrought steels except that they have a higher molybdenum content and a lower manganese content.

Phosphorus can reduce the temperature used for sintering. It forms a liquid phase, giving rapid pore rounding, strengthening, and toughening when used in amounts of 0.45 to 0.80% P. It also reduces the hysteresis losses in magnetic core applications. The hot shortness that phosphorus causes in wrought steels is generally not a problem in P/M materials. Some prealloyed steels with extra molybdenum and manganese, when blended with 2% Cu and eutectoid carbon, have enough hardenability to air harden during normal belt furnace sintering (Ref 5). After sintering, parts are tempered 1 h at 175 °C (350 °F).

Sulfur may be added to ferrous P/M materials to improve machinability. The amounts of sulfur used in P/M materials exceed those used in wrought steels; however, sulfur contents as high as 1.0% appear to have little effect on the mechanical properties of as-sintered compacts. Sulfur may be prealloyed to form MnS *in situ*, added as elemental sulfur to sponge iron, or added as manganese sulfide powder. The prealloyed form can decrease drill times by a factor of two (Ref 6). Small amounts of boron nitride can increase drill life by a factor of ten.

Alloying elements having oxides that are stable in typical sintering atmospheres are used sparingly, if at all, in low-alloy ferrous P/M materials. Manganese and chromium are sometimes used in very small amounts; vanadium and titanium are rarely used.

Infiltration

The infiltration of ferrous P/M materials is a common processing technique. Infiltrants, usually copper-base alloys, are placed in contact with the green compact, and the two are sintered together at a temperature above the melting point of the infiltrant. Capillary action draws the infiltrant into the ferrous compact, where it can promote the sintering of iron particles. In an alternative technique, the ferrous compact is sintered and then infiltrated in a second step. Traditionally, infiltration has allowed the manufacture of large parts on smaller presses because the green compacts can have a density as low as 6.0 to 6.2 g/cm³.

As indicated in Fig. 11 and Table 4, infiltration increases the strength, hardness, fatigue strength, and impact energy of ferrous P/M products compared to the iron-carbon matrix. Infiltration increases the density of the part and decreases variations in density. Porosity can be partly or completely eliminated by infiltration. As the infiltrant runs in under capillary action, it fills the higher-density fine-pore regions first. Recent proprietary techniques have increased unnotched impact toughness to more than 200 J (150 ft · lbf). Some of the disadvantages of infiltration are its high cost, the

likelihood of growth of the part during infiltration, and the possibility of erosion of the surface of the compact by the infiltrant (Ref 7).

Fig. 11 Effect of infiltration on transverse rupture strength of iron-carbon alloys sintered to a density of 6.4 Mg/m^3 . Combined carbon in the alloys was about 80% of the amount of graphite added to the iron powder. The amount of copper infiltrant was adjusted to fill various fractions of void space. Source: Ref 7

Heat Treatment of Ferrous P/M Materials

Ferrous P/M materials may be heat treated in the same manner as wrought or cast steels of comparable compositions. The porosity in P/M materials can cause complications, such as apparent loss of hardenability, greater depth of carburization or decarburization, and possible entrapment of quenchants. The effect of porosity on hardenability, which is exaggerated in measurements of apparent hardness, is shown in Fig. 12. The reduction in hardenability was caused by the reduced thermal conductivity of the porous sintered compact. The effect of porosity on depth of carbonitriding is shown in Fig. 13. The porosity of the sintered compact enabled the carbonitriding gas to penetrate well below the surface, hardening the compact to a greater depth. The use of vacuum carburizing for 2 to 10 min, followed by quenching, can form a definite case on low-carbon parts with a density as low as 6.8 g/cm^3 .

Fig. 12 Effect of porosity on hardenability. Compacts of F-0008 powder were pressed and sintered to various densities, then austenitized and end quenched. Apparent hardness traverses reflect both depth of hardening and density of compacts. Horizontal bars represent approximate distance over which the average amount of martensite in the microstructure exceeded 50%. Hardenability band for 1080 wrought steel, which has a higher manganese content, is included for comparison. Source: Ref 8

Fig. 13 Effect of porosity on carbonitriding. Compacts of F-0000 powder were pressed and sintered to various densities, then carbonitrided. Hardness traverses reflect both depth of carbonitrided case and density of compacts. Hardness traverse for a carbonitrided specimen of wrought 1018 steel is included for comparison.

Mechanical properties of FN-0205 sintered steels hardened and tempered in are shown Fig. 9.

Steam treating is a heat treatment sometimes applied to ferrous P/M materials. A typical treatment might be 2 h in superheated heated steam at 540 to 600 °C (1000 to 1100 °F). In such a treatment, a layer of black iron oxide (Fe₃O₄) is formed on the surfaces of the sintered part, including the surfaces of pores that are connected to the surface. The process increases the density, hardness, compressive strength, and resistance to wear and corrosion of the part. The effect of steam treating on the density and hardness of several ferrous P/M materials is given in Table 7. Steam treating can reduce the tensile strength, elongation, and impact strength below the as-sintered values (Table 8).

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Re-pressing

As a secondary mechanical forming operation performed at room temperature, repressing is done primarily to increase density, which increases mechanical and physical properties and hardness. Improvements in part dimensions can also be achieved by re-pressing. The amount of material deformation achieved with repressing is greater than in sizing because the forces used are greater than the sizing forces. The reduction in height of a ferrous part generally ranges from 3 to 5%. As with sizing, part tolerance after re-pressing depends on material type and part size.

Re-pressing generally refers to the application of high pressures on a sintered part at room temperature, while powder forging refers to processes in which a P/M preformed part is kept at an elevated temperature during the application of high pressure (see the section "Powder Forging"). At room temperature and at pressures as high as or higher than the compacting pressure, re-pressing increases the strength of a sintered P/M part by decreasing its porosity and by cold working the metal. The part is considerably strengthened, but at the expense of ductility. Resintering after re-pressing

increases the ductility and toughness of the part without diminishing its strength. Those materials that are difficult to re-press after sintering usually can be re-pressed if the sintering is done at a low temperature at which alloying cannot take place; this low-temperature sintering is called presintering. For iron alloys, presintering is done at 845 °C (1550 °F).

The effect of re-pressing on the density of ferrous P/M materials is shown in Fig. 14. The density that is achieved by re-pressing depends on the density of the sintered or presintered compact, the re-pressing pressure and lubricant, and whether the powder used was prealloyed or mixed from elemental powders.

Fig. 14 Effect of re-pressing on density of powder metallurgy compacts. Alloy steel powders (4640 composition) were compacted at various pressures, then sintered, re-pressed, and resintered. For each specimen, the final density is indicated by the intersection between the curve that indicates the re-pressing pressure and the grid line that indicates the green compacting pressure. Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Powder Forging*

Powder forging is a process in which unsintered, presintered, or sintered powder metal preforms are hot formed in confined dies. The process is sometimes called P/M forging or P/M hot forming, or is simply referred to by the acronym P/F.

Powder forging is a natural extension of the conventional press and sinter (P/M) process, which has long been recognized as an effective technology for producing a great variety of parts to net or near-net shape. Figure 15 shows the powder forging process. In essence, a porous preform is densified by hot forging with a single blow. Forging is carried out in heated, totally enclosed dies, and virtually no flash is generated.

Fig. 15 The powder forging process

The shape, quantity, and distribution of porosity in P/M and P/F parts strongly influence their mechanical performance. Powder forging is a deformation processing technology aimed at increasing the density of P/M parts and thus their performance characteristics.

There are two basic forms of powder forging:

- Hot upsetting, in which the perform experiences a significant amount of lateral material flow
- Hot re-pressing, in which material flow during densification is mainly in the direction of pressing. The form of densification is sometimes referred to as hot restriking, or hot coining

While P/F parts are primarily used in automotive applications where they compete with cast and wrought products, parts have also been developed for military and off-road equipment.

The economics of powder forging have been reviewed by a number of authors (Ref 10, 11, 12, 13, 14, 15). Some of the case histories included in the section "Applications of Powder Forged Parts" in this article compare the cost of powder forging with that of alternative forming technologies.

Material Considerations

The initial production steps of powder forging (performing and sintering) are identical to those of the conventional press and sinter P/M process. Certain defined physical characteristics and properties are required in the powders used in these processes. In P/M parts, surface finish is related to the particle size distribution of the powder. In powder forging, however, the surface finish is directly related to the finish of the forging tools.

Typical pressing grades are -80 mesh with a median particle size of about 75 μm . The apparent density and flow are important for maintaining fast and accurate die filling. The chemistry affects the final alloy produced, as well as the compressibility.

Green strength and compressibility are more critical in P/M than they are in P/F applications. Although there is a need to maintain edge integrity in P/F preforms, there are rarely thin, delicate sections that require high green strength. Because P/F preforms do not require high densities (typically 6.2 to 6.8 g/cm³), the compressibility obtainable with prealloyed powders is sufficient. However, carbon is not prealloyed because it has an extremely detrimental effect on compressibility.

The two principal requirements for P/F materials are a capability to develop an appropriate hardenability that will guarantee strength and to control fatigue performance by microstructural features such as inclusions.

Hardenability. Nickel and molybdenum have the advantage that their oxides are reduced at conventional sintering temperatures. Alloy design is therefore a compromise, and the majority of atomized prealloyed powders in commercial use are nickel/molybdenum based, with manganese present in limited quantities. The compositions of three commercial P/M steels are:

Alloy	Composition, wt% ^(a)		
	Mn	Ni	Mo
P/F-4600	0.10-0.25	1.75-1.90	0.50-0.60
P/F-2000	0.25-0.35	0.40-0.50	0.55-0.65
P/F-1000	0.10-0.25

(a) All compositions contain balance of iron.

The higher cost of nickel and molybdenum, along with the higher cost of powder, compared with conventional wrought materials, is often offset by the higher material utilization inherent in the P/F process.

More recently, P/F parts have been produced from iron powders (0.10 to 0.25% Mn) with copper and/or graphite additions for parts that do not require the heat-treating response or high-strength properties achieved through the use of the low-alloy steels.

Inclusion Assessment. Because the properties of material powder forged to near-full density are strongly influenced by the composition, size distribution, and location of nonmetallic inclusions (Ref 16, 17, 18), a method has been developed for assessing the inclusion content of powders intended for P/F applications (Ref 19, 20, 21, 22). Samples of powders intended for forging applications are re-press powder forged under closely controlled laboratory conditions. The resulting compacts are sectioned and prepared for metallographic examination. The inclusion assessment technique involves the use of automatic image analysis equipment. The compact used for inclusion assessment may also be used to measure the amount of unalloyed iron powder particles present.

Process Considerations

The development of a viable powder forging system requires the consideration of many process parameters. The mechanical, metallurgical, and economic outcomes depend to a large extent on operating conditions, such as temperature, pressure, flow/feed rates, atmospheres, and lubrication systems. Equally important consideration must be given to the types of processing equipment, such as presses, furnaces, dies, and robotics, and to secondary operations, in order to obtain the process conditions that are most efficient. This efficiency is maintained by optimizing the process line layout.

Examples of effective equipment layouts for performing, sintering, reheating, forging, and controlled cooling have been reviewed in the literature (Ref 10). Figure 16 shows a few of the many possible operational layouts. Each of these process stages is reviewed in the following sections.

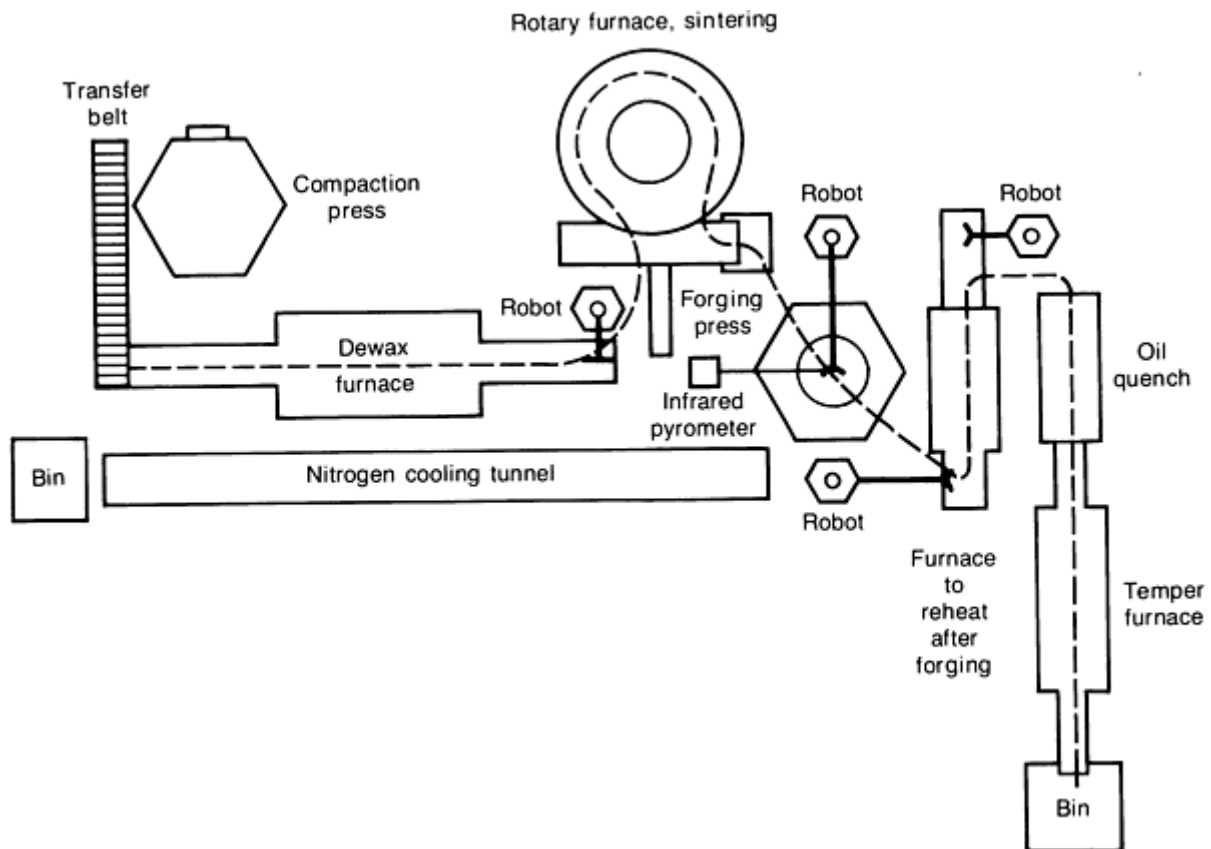

Fig. 16 A powder forging process line. Source: Ref 23

Preforming. Preforms are manufactured from admixtures of metal powders, lubricants, and graphite. Compaction is predominantly accomplished in conventional P/M presses that use closed dies.

The control of weight distribution within preforms is essential to produce full density and thus maximize performance in the critical regions of the forged component. Excessive weight in any region of the preform may cause overload stresses that could lead to tool breakage at forging.

Successful preform designs have been developed by an iterative trial-and-error procedure, using prior experience to determine the initial shape. More recently, computer-aided design (CAD) has been used for preform design.

Preform design is intimately related to the design and dimensions of the forging tooling, the type of forging press, and the forging process parameters. Among the variables to be considered for the preforming tools are:

- Temperature, that is, preform temperature, die temperature, and, when applicable, core rod temperature
- Ejection temperature of the forged part
- Lubrication conditions, that is, influence on compaction/ejection forces and tooling temperatures
- Transfer time and handling of the preform from the preheat furnace to the forging die cavity

Correct preform design not only entails having the right amount of material in the various regions of the preform, but also is concerned with material flow between the regions and prevention of potential fractures and defects (Fig. 17).

Fig. 17 Configuration for the ring preform (a) for forging the part shown in (b). (b) Cross section of the part under consideration for powder forging

Sintering and Reheating. Preforms may be forged directly from the sintering furnace; sintered, reheated, and forged; or sintered after the forging process. The basic requirements for sintering in a ferrous P/F system are:

- Lubricant removal
- Oxide reduction
- Carbon diffusion
- Development of particle contacts
- Heat for hot densification

Oxide reduction and carbon diffusion are the most important aspects of the sintering operations. For most ferrous powder forging alloys, sintering takes place at about 1120 °C (2050 °F) in a protective reducing atmosphere with a carbon potential to prevent decarburization. Typical P/M sintering has been performed at 1120 °C (2050 °F) for 20 to 30 min. Increases in temperature will reduce the time required for sintering by improving oxide reduction and increasing carbon

diffusion. Chromium-manganese steels have been limited in their use because of the higher temperatures required to reduce their oxides and the greater care needed to prevent reoxidation.

Any of the furnaces used for sintering P/M parts, such as vacuum, pusher, belt, rotary hearth, walking beam, roller hearth, and batch/box, may be used for sintering or reheating P/F preforms. The sintered preforms may be forged directly from the sintering furnace; stabilized at lower temperatures and forged; or cooled to room temperature, reheated, and forged. All cooling, temperature stabilization, and reheating must occur under protective atmosphere to prevent oxidation.

Induction furnaces are often used to reheat axisymmetric preforms to the forging temperature because of the short time required to heat the material. Difficulties may be encountered in obtaining uniform heating throughout asymmetric shapes because of the variation in section thickness.

Powder forging involves removing heated preforms from a furnace, usually by robotic manipulators, and locating them in the die cavity for forging at high pressures (690 to 965 MPa, or 100 to 140 ksi). Preforms may be graphite coated to prevent oxidation during reheating and transfer to the forging die. Lubrication of the die and punches is usually accomplished by spraying a water-graphite suspension into the cavity.

The forging presses commonly used in conventional forging, including hammers, high energy rate forming machines, mechanical presses, hydraulic presses, and screw presses, have been evaluated for use in powder forging. The essential characteristics that differentiate presses are contact time, stroke velocity, available energy and load, stiffness, and guide accuracy.

Metal Flow in Powder Forging. Draft angles, which facilitate forging and ejection in conventional forging, are eliminated in P/F parts. This means that greater ejection forces--on the order of 15 to 20% of press capacity as a minimum--are required for the powder forging of simple shapes. However, the elimination of draft angles permits P/F parts to be forged closer to net shape.

Tool Design. In order to produce sound forged components, the forging tooling must be designed to take into account:

- Preform temperature
- Die temperature
- Forging pressure
- The elastic strain of the die
- The elastic/plastic strain of the forging
- The temperature of the part upon ejection
- The elastic strain of the forging upon ejection
- The contraction of the forging during cooling
- Tool wear

Secondary Operations. In general, the secondary operations applied to conventional components, such as plating and peening, may be applied to P/F components. The most commonly used secondary operations involve deburring, heat treating, and machining.

The heat treatment of P/M products is the same as that required for conventionally processed materials of similar composition. The most common heat-treating practices involve treatments such as carburizing, quench and temper cycles, and continuous-cooling transformation.

The amount of machining required for P/F components is less than the amount required for conventional forgings because of the improved dimensional tolerances. Standard machining operations may be used to achieve final dimensions and surface finish. One of the main economic benefits of powder forging is the reduced amount of machining required. Improved machinability can be accomplished by the addition of solid lubricants such as manganese sulfide.

Mechanical Properties

Wrought steel bar stock undergoes extensive deformation during cogging and rolling of the original ingot. This creates inclusion stringers and leads to planes of weakness, which affect the ductile failure of the material. The mechanical

properties of wrought steels vary considerably with the direction test pieces are cut from the wrought billet. Powder forged materials, on the other hand, undergo relatively little material deformation, and their mechanical properties have been shown to be relatively isotropic.

The mechanical properties of P/F materials are usually intermediate to the transverse and longitudinal properties of wrought steels. The rotating-bending fatigue properties of P/F material have also been shown to fall between the longitudinal and transverse properties of wrought steel of the same tensile strength.

While the performance of machined laboratory test pieces follows the intermediate trend described above, in the case of actual components, P/F parts have been shown to have superior fatigue resistance. This has generally been attributed not only to the relative mechanical property isotropy of powder forgings, but also to their better surface finish and finer grain size.

This section reviews the mechanical properties of P/F materials. The data presented represent results obtained on machined standard laboratory test pieces. Data are reported for four primary materials. The first two material systems are based on prealloyed powders (P/F-4600 and P/F-4200; see the section "Hardenability" in this article). The third material, based on an iron-copper-carbon alloy, was used by Toyota in 1981 to make P/F connecting rods; Ford Motor Company introduced powder forged rods with a similar chemistry in 1986. Mechanical property data are therefore presented for copper and graphite powders mixed with an iron powder base to produce materials that generally contain 2% Cu. Some powder forged components are made from plain carbon steel. This is the fourth and final material for which mechanical property data are presented.

Forging Mode. It is well known that the forging mode has a major effect on the mechanical properties of components. With this in mind, the mechanical property data reported in this section were obtained on specimens that were either hot upset or hot re-press forged.

Heat Treatments. There were three heat treatments used in developing the properties of the prealloyed powder forged materials: case carburizing, blank carburizing, and through-hardening (quenching and tempering).

Hardenability. Jominy hardenability curves are presented in Fig. 18 for the P/F-4600, P/F-4200, and iron-copper-carbon alloys. Testing was carried out according to ASTM A 255. Specimens were machined from upset forged billets that had been sintered at 1120 °C (2050 °F) in associated ammonia.

Fig. 18 Jominy hardenability curves for (a) P/F-4600, (b) P/F-4200, and (c) iron-copper-carbon materials at various forged-carbon levels. Vickers hardness was determined at a 30 kgf load.

Tensile, Impact, and Fatigue Properties. Tensile properties were determined on test pieces with a gage length of 25 mm (1 in.) and a gage diameter of 6.35 mm (0.25 in.). Testing was carried out according to ASTM E 8 using a crosshead speed of 0.5 mm/min (0.02 in./min). Room-temperature impact testing was carried out on standard Charpy V-notch specimens according to ASTM E 23. Rotating-bending fatigue (RBF) testing was performed using single-load, cantilever, rotating fatigue testers. The tensile, impact, and fatigue data for the various materials are summarized in Tables 9, 10, and 11.

(a) Still-air cooled.

(b) Forced-air cooled.

The iron-copper-carbon alloys were either still-air cooled or forced-air cooled from the austenitizing temperature of 845 °C (1550 °F). The austenitizing temperature influences core hardness. These iron-copper-carbon alloys are often used with manganese sulfide additions for enhanced machinability. The tensile, impact, and fatigue properties for a sample with a 0.35% manganese sulfide addition are compared with a material without sulfide additions in Table 12. Data from the samples with manganese sulfide and sulfurized powders are included for comparison. The manganese sulfide addition had little influence on tensile strength, whereas the sulfurization process degraded tensile properties.

Table 12 Mechanical property and fatigue data for iron-copper-carbon alloys with sulfur additions

Quality Assurance for P/F Parts

Many of the quality assurance tests applied to wrought parts are similar to those used for powder forged parts. Among the parameters specified are part dimensions, surface finish, magnetic particle inspection, composition, density, metallographic analysis, and nondestructive testing.

Part Dimensions and Surface Finish. Typical tolerances for P/F parts are summarized in Table 15. The as-forged surface finish of a P/F parts is directly related to the surface finish of the forging tool. Surface finish is generally better than 0.8 μm (32 $\mu\text{in.}$) which is better than that obtained on wrought forged parts. This good surface finish is beneficial to the fatigue performance of P/F parts.

Table 15 Typical tolerances for P/F parts

Dimension or characteristic	Description	Typical tolerance		Minimum tolerance		Schematic of part
		mm/mm	in./in.	mm	in.	
<i>a</i>	Linear dimension perpendicular to the press axis	0.0025	0.0025	0.08	0.003	
<i>b</i>	Linear dimensions parallel to the press axis	±0.25	±0.10	0.20	0.008	
<i>c</i>	Concentricity of holes to external dimensions	0.10	0.004	
<i>d</i>	Surface finish	Normally better than 0.8 μm (32 μin.)		

Magnetic particle inspection is used to detect surface blemishes such as cracks and laps.

Density. Sectional density measurements are taken to ensure that sufficient densification has been achieved in critical areas. Displacement density checks are generally supplemented by microstructural examination to assess the residual porosity level. For a given level of porosity, the measured density will depend on the exact chemistry, thermomechanical condition, and microstructure of the sample. Parts may be specified to have a higher density in particular regions than is necessary in less critical sections of the same component.

Metallographic Analysis. Powder forged parts are subjected to extensive metallographic evaluation. The primary parameters of interest include those discussed below.

The extent of surface decarburization permitted in a forged part will generally be specified. The depth of decarburization may be estimated by metallographic examination, but it is best quantified using microhardness measurements as described in ASTM E 1077.

Surface finger oxides are defined as oxides that follow prior particle boundaries into the forged part from the surface and cannot be removed by physical means such as rotary tumbling. An example of surface finger oxides is shown in Fig. 19. Metallographic techniques are used to determine the maximum depth of surface finger oxide penetration.

Fig. 19 Surface finger oxides (arrows at upper right) and interparticle oxide networks (arrow near lower left) in a powder forged material

Interparticle oxides follow prior particle boundaries. They may sometimes form a continuous three-dimensional network, but more often will, in a two-dimensional plane of polish, appear to be discontinuous. An example is presented in Fig. 19.

Unalloyed iron powder contamination in low-alloy powder forged parts can be quantified by means of the etching procedure described in the earlier section "Material Considerations."

The nonmetallic inclusion level in a P/F part may also be quantified using the image analysis technique described in the section "Material Considerations." However, if the section of a component selected for inclusion assessment is not pore-free, image analysis procedure are not applicable.

Nondestructive Testing. Although metallographic assessment of P/F parts is common, it is also useful to have a nondestructive method for evaluating the microstructural integrity of components. It has been demonstrated that this can be achieved with a magnetic bridge comparator.

Applications of Powder Forged Parts

Previous sections compared powder forging and drop forging and illustrated the range of mechanical property performance that can be achieved in powder forged material. The present section concentrates on two examples of P/F components and highlights some of the reasons for selecting P/F parts over those made by competing forming methods.

Example 1: Converter Clutch Cam.

The automotive industry is the principal user of P/F parts, and components for automatic transmissions represent the major areas of application. One of the earliest powder forgings used in such an application is the converter clutch cam (Fig. 20). The primary reason that powder forging was chosen over competitive processes was that it reduced manufacturing costs by 58%, compared with the conventional process of machining a forged gear blank.

Fig. 20 Powder forged converter clutch cam used in an automotive automatic transmission. Courtesy of Precision Forged Products Division, Federal Mogul Corporation

Powder forged cams are made from a water-atomized steel powder (P/F-4200) containing 0.6% Mo, 0.5% Ni, 0.3% Mn, and 0.3% graphite. Preforms weighing 0.33 kg (0.73 lb) are compacted to a density of 6.8 g/cm³. The preforms are sintered at 1120 °C (2050 °F) in an endothermic gas atmosphere with a 2 °C (35 °F) dewpoint. The sintered preforms are graphite coated before being induction heated and forged to near-full density (less than 0.2% porosity) using both axial and lateral flow. After forging, the face of the converter clutch cam is ground, carburized to a depth of 1.75 mm (0.070 in.), and surface hardened by means of induction. The part requires a high density to withstand the high Hertzian stress experienced by the inner cam surface in service. Machining requires only one step on the P/F cam; seven machining operations were required for the conventionally processed cam.

Example 2: Powder Forged Connecting Rods.

Connecting rods were among the components selected for a number of P/F development programs in the 1960s. However, it was not until 1976 that the first P/F connecting rod was produced commercially. This was the connecting rod for the Porsche 928 V-8 engine.

The connecting rod for the Porsche 928 engine was made from a water-atomized low-alloy steel powder (0.3 to 0.4% Mn, 0.1 to 0.25% Cr, 0.2 to 0.3% Ni, and 0.25 to 0.35% Mo) to which graphite was added to give a forged carbon content of

0.35 to 0.45%. The forgings were oil quenched and tempered to a core hardness of 28 HRC (ultimate tensile strength of 835 to 960 MPa, or 121 to 139 ksi), followed by shot peening to a surface finish of 11 to 13 on the Almen scale.

The preform was designed so that the P/F component had less than 0.2% porosity in the critical web region. The P/F connecting rod had considerably better fatigue properties than did conventional drop forged rods. Its weight control was good enough to allow a reduction in the size of the balance pads, resulting in a weight savings of about 10% (it weighed ~1 kg, or 2 lb). Powder forged connecting rods are currently used in both the Porsche 928 and 944 engines.

The first high-volume commercialization of P/F connecting rods was in the 1.9 L Toyota Camry engine. In this design, the balance pads were completely eliminated. Despite the publication of the results of development trials in 1972, it was not until the summer of 1981 that production rods were introduced.

Toyota selected a copper steel (Fe-0.55C-2Cu) based on a water-atomized iron powder to replace conventional forgings, which had been made from a quenched and tempered 10L55 free-machining steel. The preform, which has a preshaped partial I-beam web section, has an average green density of 6.5 g/cm³. The preform shape is such that forging is predominantly in the re-pressing mode. However, some lateral flow does take place where required in critical regions, such as the web.

Preforms are sintered for 20 min at 1150 °C (2100 °F) in an endothermic gas atmosphere in a specially designed rotary hearth furnace. During sintering, the preforms are supported on flat, ceramic plates. The preforms are allowed to stabilize at about 1010 °C (1850 °F) before closed-die forging.

Exposure of the preform to the atmosphere during transfer to the forging dies is limited to 4 to 5 s. An ion nitriding treatment is applied to the punches and dies in the regions at which forging deformation occurs. The connecting rods are forged at the rate of 10 per minute, and tool lives of over 100,000 pieces have been reported.

The forged rods are subjected to a thermal treatment after forging. This results in a ferrite/pearlite microstructure with a core hardness of 240 to 300 HV (30 kgf load). Subsequent operations include burr removal, shot peening, straightening, sizing, magnetic particle inspection, and finish machining.

Savings in material and energy are substantial for the P/F rods. The billet weight for a conventional forging is 1.2 kg (2.65 lb); the P/F preform weighs 0.7 kg (1.54 lb) and requires little machining. In addition to the benefits in process economics, the variability in fatigue performance for the P/F rods is reported to be half that of conventionally forged parts.

Ford Motor Company has introduced P/F connecting rods in the 1.9 L four-cylinder engine used in the Ford Escort model. Five million connecting rods were in service by June 1989. Figure 21 illustrates the Ford P/F connecting rod. Ford has also announced plans to use P/F rods in its modular engine, which is scheduled for production in 1992.

Fig. 21 Powder forged connecting rod for 1.9 L automobile engine. A similar rod will be used in the modular engine.

Ferrous Powder Metallurgy Materials

Revised by Leander F. Pease III, Powder-Tech Associates, Inc.

Metal Injection Molding (MIM) Technology

When 60 vol% of fine (10 μ m, or 400 μ in.) metal powder is blended with 40 vol% lubricant and binder, the resulting mixture can be injection molded, much like a conventional plastic. Any shape that can be molded in plastic can be molded in metal powder. The use of paraffin waxes and thermoplastics such as polyethylene or polypropylene provides the rheological basis for allowing the mixture to flow around corners and into undercuts in a way that is impossible in the uniaxial pressing of binder-free metal powders. The process leads to a whole new class of P/M geometries.

In the original 1971 Wiech process, the wax is removed with a liquid solvent. The remaining plastic binder is thermally removed during a very careful heat-up and sintering. The latter process takes 3 to 5 days. During the long debinding and sintering cycle at 1200 to 1300 °C (2200 to 2400 °F), near-theoretical density is reached. Following further development at Witec, the process (Wiech II) now consists of removal of the wax in air, at about 175 °C (350 °F), over a 1 to 3 day

period. This oxidizes the part, resulting in a brownish color, while the oxide imparts extra strength for handling. Sintering takes place in a closed reaction vessel in a controlled atmosphere of argon and hydrogen. The 60% dense as-molded parts shrink 14 to 20% and achieve near-full density (>95% dense). The parts have very fine, noninterconnected porosity and much better elongation, toughness, and dynamic properties than conventionally pressed and sintered materials. Such parts are limited to section sizes of 9.5 to 13 mm (0.375 to 0.5 in.) and have tolerances of ± 0.003 mm/mm (± 0.003 in./in.). Because of the oxidation that occurs during wax removal, the process may be fundamentally limited to smaller cross sections. Also, the oxidation of sensitive elements such as chromium and manganese is only reversed at later sintering, with difficulty. Modification of the early Wiech process using solvent to debinder the wax, is now the most commonly used debinding technique. The residual thermoplastic can be handled in a vacuum furnace or atmosphere pusher furnace.

The Rivers process, licensed by Haynes International, uses methylcellulose as a binder, along with small amounts of water, glycerine, and boric acid. The methylcellulose dissolves in cold water to form a binder. Upon injection into a warm mold, it gels to form a fairly rigid part that can be removed from the tooling. The part is dried at 120 °C (250 °F) to remove water and then sintered by any convenient sintering process. This can be done in belt furnaces, pushers, or vacuum furnaces, at nearly any heat-up rate. Depending on the fineness of the starting powder and the sintering temperature, densities of 90 to 99% of full density are obtained. An injection molded and sintered 6.8 kg (15 lb) Stellite block has demonstrated the capability to make parts with a 75 mm (3 in.) thick section. This degree of binder removal is possible because the methyl cellulose breaks down easily upon heat-up and follows the channels created by the evaporated water.

Although there are some large-scale users of the Wiech-type batch sintering reactors in Japan (340 kg, or 750 lb, in a 60 h period), the trend in the United States is toward more continuous furnaces. The use of a 1315 °C (2400 °F) molybdenum wound pusher furnace has become widespread. A single-stage vacuum furnace to evaporate and thermally remove all binders and lubricants from MIM parts has been developed. It is an outgrowth of vacuum furnaces, which have long been used to dewax and liquid phase sinter carbide parts. The MIM parts are then heated to sintering temperatures of 1100 to 1315 °C (200 to 2400 °F). Because the parts are not oxidized, the process works well with sensitive chromium- and manganese-containing materials, as well as low-alloy steel. A 45 kg (100 lb) load has a floor-to-floor time of 12 h or less and runs under microprocessor control.

Advantages of the MIM Process. The tolerance and shape factor advantages were noted above. The design engineer should think of using injection molded parts in mechanisms or as small enclosures. Some of the MIM fabricators produce runs of 2000 to 5000 pieces, particularly on more expensive parts. They can do a short run such as these because there is no danger to the tooling at setup, while in conventional P/M there is more risk. As the process becomes ever better understood and better controlled, small batches can be grouped together for sintering. Sintering to near-full density seems to reach an end point for shrinkage. This contributes to product uniformity, as long as the original molded part has uniform metal powder density.

Because the process uses fine powders (5 to 20 μm), alloys have been formed *in situ* by the diffusion of mixed elements or master alloys. Some stainless steel alloys have been made in this way, using an Fe-30Cr master alloy. It is convenient to make 4100 series alloys without the need for prealloyed powders. The capability to blend an alloy allows a flexibility that does not exist in conventional powder metallurgy. There are only a limited number of prealloyed powders available.

Sintering to near-full density gives excellent toughness, elongation, and other dynamic properties. This is aided by the presence of fine spheroidized porosity versus the sharp, stress raiser porosity of conventional powder metallurgy (see Fig. 22 for a MIM microstructure). Without open pores, the parts can be plated, used in pressure-controlled environments, or used in food handling applications. The stainless steels thus produced have very low carbon contents and are more corrosion resistant than typical P/M materials.

Fig. 22 Typical MIM microstructure with rounded, isolated areas of porosity. BASF grade OM carbonyl iron sintered for 1 h at 1315 °C (2400 °F) in vacuum. 94% of full density. Unetched. 180×

The capital equipment (presses) for injection molding is more economical than that for large-scale P/M presses. Tool life is at least 300,000 pieces. These factors help offset the added short-term material cost.

Factors Impeding Growth of MIM Technology. In conventional press and sinter P/M, dimensional tolerances and quality control are very significant. Re-pressed or coined P/M parts are made to a tolerance of ± 0.013 mm (± 0.0005 in.) on a 25 mm (1 in.) diam part. As-sintered tolerances on well-behaved alloys are ± 0.001 mm/mm (± 0.001 in./in.). Most MIM producers are achieving ± 0.003 mm/mm (± 0.003 in./in.) with some companies offering 0.001 mm/mm (0.001 in./in.) on selected dimensions. The industry as a whole needs to reach the tolerance levels being offered by conventional powder metallurgy. Some MIM producers do re-press their parts to straighten them and achieve tolerances like those of conventional powder metallurgy.

The raw materials are expensive: in 1989, carbonyl Fe, reduced, is \$8.60/kg (\$3.90/lb). With binder added, ferrous material costs may be \$7 to 10/kg (\$3.20 to 4.50/lb). The total cost for low-alloy steel MIM parts is \$30 to 40/kg (\$14 to 18/lb). This explains why parts of less than 20 g (0.7 oz) have been the initial focus of sales activity. Work is underway on ways to liquid phase sinter mixtures of \$0.70/kg (\$0.32/lb) iron and a special graphite (Ref 24). At 1150 °C (2100 °F), some regions of the iron-graphite parts do sinter to full density, but the process is not yet successful. The development of sintering techniques for the coarser, less expensive powders will enormously impact the economics of the process. There are several Japanese and U.S. companies at work developing a way to make less expensive fine Fe powders or alloys.

MIM green parts can exhibit defects as they exit the press. Variations in metal loading or the segregation of metal and plastic will result in dimensional variations as full density is approached. Real-time x-ray equipment has disclosed voids and low density areas in injection molded ceramic parts with diameters of 0.1 mm (0.004 in.). It also may be possible to measure density variation and to look for cracks and pores in MIM parts with x-ray equipment.

Mechanical Properties. Typical mechanical properties for 95% dense MIM materials are given in Table 16. The Metal Injection Molding Association and ASTM Subcommittee B09.11 are currently developing the standardized minimum properties for the MIM materials that are in current use. These will be available in 1990. Figure 23 shows the new standard tensile test bar for metal injection molded materials. It is pulled by inserting pins through the holes in each end and is self-aligning.

Table 16 Mechanical properties of metal injection molded materials

Alloy	Condition	Ultimate tensile strength	0.2% offset yield strength	Elongation in 25 mm (1 in.), %	Hardness	Processing

		MPa	ksi	MPa	ksi	%		
Fe-2Ni-0.43C	Sintered	470	68	255	37	21	74 HRB	Sinter
	Heat treated	1450	210	1095	159	4.0	38 HRC	Sinter, heat treat, then hold 1 h at 232 °C (450 °F)
	Heat treated	1125	163	980	142	5.5	31 HRC	Sinter, heat treat, then hold 1 h at 343 °C (650 °F)
	Heat treated	880	128	710	103	11.0	21 HRC	Sinter, heat treat, then hold 1 h at 427 °C (800 °F)
4600 + 0.45% C	Sintered	605	88	345	50	11.5	79 HRB	Sinter
	Heat treated	1620	235	1350	196	2.5	44 HRC	Sinter, heat treat, then hold 1 h at 232 °C (450 °F)
	Heat treated	1345	195	1115	162	4.5	78 HRC	Sinter, heat treat, then hold 1 h at 343 °C (650 °F)

Applications. MIM parts have been used in a variety of production parts for automobiles. Other applications of MIM materials include the molding of threads on pressure manifolds and the fabrication of gun sight parts with a special nongalling cam locking mechanism that could not be machined on the parts.

The first two MIM production parts in automobiles were a part for an ignition lock (Fig. 24) and a single-part replacement (Fig. 25a) for a two-part turn signal lever assembly (Fig. 25b). Both have been in service since July 1988.

Fig. 24 MIM part (upper left) for an automobile ignition lock. The key forces the MIM part into contact with a security switch. Courtesy of SSI Technologies

Fig. 25 Single-piece MIM part (a) that replaced a two-piece automobile turn signal lever assembly (b). The smaller MIM part in (a) was the first version, while the larger MIM part is the finished version that replaced the two-part assembly shown in (b). Courtesy of the Remington Arms Division of E.I. Du Pont de Nemours & Company, Inc.

Figure 24 shows the entire ignition lock and the MIM subcomponent. As the key is inserted in the lock, the cam-shaped MIM part moves away and depresses an electrical switch, which is part of the security system. The initial design of the part was too small and complicated for the model shop to make and it was prototyped from the MIM tooling.

The turn signal indicator lever is an example of the replacement of a two-piece assembly (Fig. 25b) with a single MIM part. The lower portion of Fig. 25(a) shows the first version of the MIM part, and the upper view shows the final 19.0 g (0.670 oz) MIM part that replaced the assembly. The MIM material is iron with 2% Ni, sintered and then case hardened. It replaced AISI 4037 and SAE 1018 case hardened. The MIM part succeeded because of its superior strength compared to the two-piece assembly. The core properties of the materials are 415 MPa (60 ksi) tensile strength and 15% elongation at 60 HRB.

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Introduction

THE ORIGINAL AUSTENITIC manganese steel, containing about 1.2% C and 12% Mn, was invented by Sir Robert Hadfield in 1882. Hadfield's steel was unique in that it combined high toughness and ductility with high work-hardening capacity and, usually, good resistance to wear. Consequently, it rapidly gained acceptance as a very useful engineering material.

Hadfield's austenitic manganese steel is still used extensively, with minor modifications in composition and heat treatment, primarily in the fields of earthmoving, mining, quarrying, oil well drilling, steelmaking, railroading, dredging, lumbering, and in the manufacture of cement and clay products. Austenitic manganese steel is used in equipment for handling and processing earthen materials (such as rock crushers, grinding mills, dredge buckets, power shovel buckets and teeth, and pumps for handling gravel and rocks). Other applications include fragmentizer hammers and grates for automobile recycling and military applications such as tank track pads. Another important use is in railway trackwork at frogs, switches, and crossings, where wheel impacts at intersections are especially severe. Because austenitic manganese steel resists metal-to-metal wear, it is used in sprockets, pinions, gears, wheels, conveyor chains, wear plates, and shoes.

Austenitic manganese steel has certain properties that tend to restrict its use. It is difficult to machine and usually has a yield strength of only 345 to 415 MPa (50 to 60 ksi). Consequently, it is not well suited for parts that require close-tolerance machining or that must resist plastic deformation when highly stressed in service. However, hammering, pressing, cold rolling, or explosion shocking of the surface raises the yield strength to provide a hard surface on a tough core structure.

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Composition

Many variations of the original austenitic manganese steel have been proposed, often in unexploited patents, but only a few have been adopted as significant improvements. These usually involve variations of carbon and manganese, with or without additional alloys such as chromium, nickel, molybdenum, vanadium, titanium, and bismuth. The most common of these compositions, as listed in ASTM A 128, are given in Table 1.

Table 1 Standard composition ranges for austenitic manganese steel castings

ASTM A 128 grade	Composition, %						
	C	Mn	Cr	Mo	Ni	Si (max)	P (max)
A	1.05-1.35	11.0 min	1.00	0.07

B-1	0.9-1.05	11.5-14.0	1.00	0.07
B-2	1.05-1.2	11.5-14.0	1.00	0.07
B-3	1.12-1.28	11.5-14.0	1.00	0.07
B-4	1.2-1.35	11.5-14.0	1.00	0.07
C	1.05-1.35	11.5-14.0	1.5-2.5	1.00	0.07
D	0.7-1.3	11.5-14.0	3.0-4.0	1.00	0.07
E-1	0.7-1.3	11.5-14.0	...	0.9-1.2	...	1.00	0.07
E-2	1.05-1.45	11.5-14.0	...	1.8-2.1	...	1.00	0.07
F	1.05-1.35	6.0-8.0	...	0.9-1.2	...	1.00	0.07

The available assortment of wrought grades is smaller and usually approximates ASTM composition B-3. Some wrought grades contain about 0.8% C and either 3% Ni or 1% Mo. Large heat orders are usually required for the production of wrought grades, while cast grades and their modifications are more easily obtained in small lots. A manganese steel foundry may have several dozen modified grades on its production list. Modified grades are usually produced to meet the requirements of application, section size, casting size, cost, and weldability considerations.

Carbon and Manganese. The ASTM A 128 compositions in Table 1 do not permit any austenite transformation when the alloys are water quenched from above the A_{cm} (that is, the temperature that corresponds to the boundary between the cementite-austenite and the austenite fields). However, this does not preclude lower ductility in heavy sections because of slower quenching rates. The effect is due to the formation of carbides along grain boundaries and other interdendritic areas and to some degree affects nearly all commercial castings except the very smallest. Figure 1 shows A_{cm} temperatures for 13% Mn steels containing between 0.6 and 1.4% C. Figure 2 shows the effects of carbon and manganese content on the M_s temperature, that is, the temperature at which martensite starts to form from austenite upon cooling, of a homogeneous austenite with all carbon and manganese in solid solution.

Fig. 1 Solubility of carbon in 13% Mn steels. Source: Ref 1

Fig. 2 Variation of M_s temperature with carbon and manganese contents. Source: Ref 2

The mechanical properties of austenitic manganese steel vary with both carbon and manganese content. Figure 3 indicates that carbon increases strength up to the range of ASTM A 128, grade A. A plateau is indicated at 1.05 to 1.35% C content. Any departure from this curve can be attributed to grain size unless good statistical evidence is found. The plateau at 827 MPa (120 ksi) is based on the 97-heat, 270-test scatter graph shown in Fig. 4. The data points on Fig. 4 were used to calculate the standard deviation, σ , data in Fig. 3. As carbon is increased it becomes increasingly difficult to retain all of the carbon in solid solution, which may account for reductions in tensile strength and ductility. Nevertheless, because abrasion resistance tends to increase with carbon, carbon content higher than the 1.20% midrange of grade A may be preferred even when ductility is lowered. Carbon content above 1.4% is seldom used because of the difficulty of obtaining an austenitic structure sufficiently free of grain boundary carbides, which are detrimental to strength and

ductility. The effect can also be observed in 13% Mn steels containing less than 1.4% C because segregation may result in local variations of $\pm 17\%$ ($\pm 0.2\% \text{C}$) from the average carbon level determined by chemical analysis.

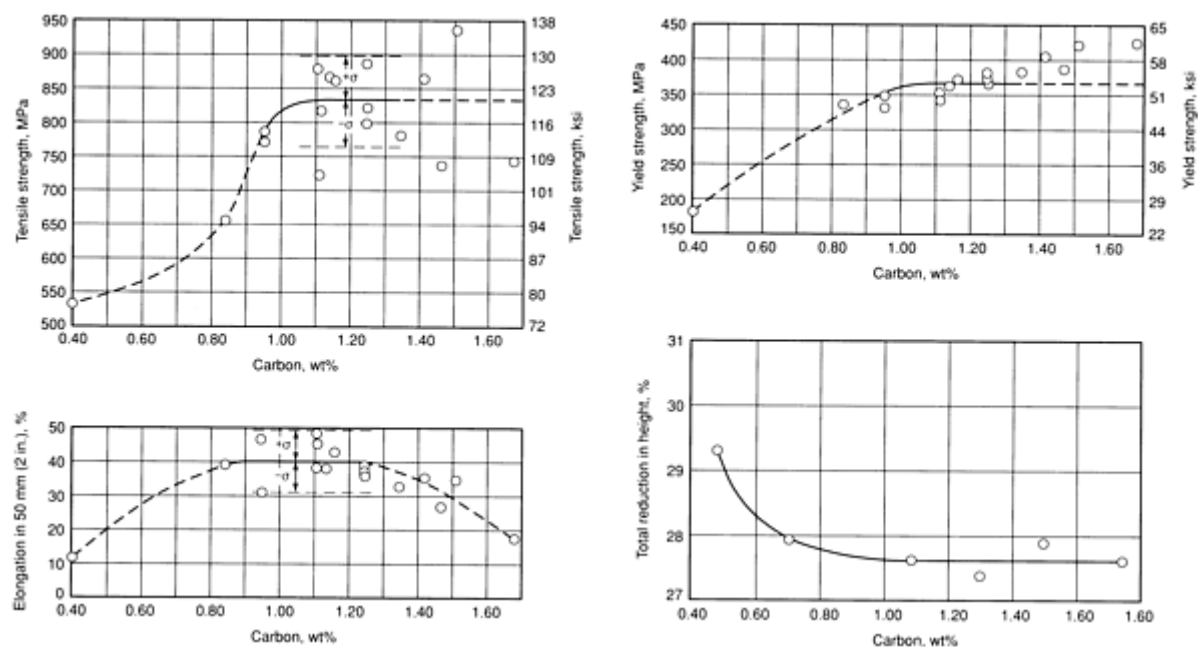

Fig. 3 Variation of properties with carbon content for austenitic manganese steel containing 12.2 to 13.8% Mn. Data are for castings weighing 3.6 to 4.5 kg (8 to 10 lb) and about 25 mm (1 in.) in section size that were water quenched from 1040 to 1095 °C (1900 to 2000 °F). Flow under impact is the total reduction in height sustained by a cylindrical specimen 25 mm (1 in.) in both diameter and length after absorbing 20 blows of 680 J (500 ft · lbf) each. Source: Abex Research Center

Fig. 4 Distribution of tensile strength and ductility values for 97 heats of manganese steel. The chemical compositions indicated are average for the specific data points plotted. Test specimens were 25 mm (1 in.) diam bars, austenitized and quench-annealed from 1010 °C (1850 °F) or above. Source: Ref 3

The 0.7% C (min) of grades D and E-1 may be used to minimize carbide precipitation in heavy castings or in weldments, and similar low carbon contents are specified for welding filler metal. Carbides form in castings that are cooled slowly in the molds. In fact, carbides form in practically all ascast grades containing more than 1.0% C, regardless of mold cooling rates. They form in heavy-section castings during heat treatment if quenching is ineffective in producing rapid cooling throughout the entire section thickness. Carbides can form during welding or during service at temperatures above about 275 °C (530 °F).

If carbon and manganese are lowered together, for instance to 0.53% C with 8.3% Mn or 0.62% C with 8.1% Mn, the workhardening rate is increased because of the formation of strain-induced α (body-centered cubic, or bcc) martensite. However, this does not provide enhanced abrasion resistance (at least to high-stress grinding abrasion) as is often hoped (Ref 4).

Manganese contributes the vital austenite-stabilizing effect of delaying transformation (but not eliminating it.) Thus, in a simple steel that contains 1.1% Mn, isothermal transformation at 370 °C (700 °F) begins about 15 s after the steel is quenched to that temperature, whereas in a 13% Mn steel, transformation at the same temperature does not begin until after 48 h (Ref 1). Below 260 °C (500 °F), phase changes and carbide precipitation are so sluggish that for all practical purposes they may be neglected, in the absence of deformation, if manganese content exceeds 10%.

Figure 5 shows the influence of manganese content on the strength and ductility of cast austenitic steel that has been solution treated and water quenched. It confirms the observations of many investigators, including Sir Robert Hadfield (Ref 5), who studied the influence of manganese content up to about 22%. Manganese content has little effect on yield

strength. In tensile testing, ultimate strength and ductility increase fairly rapidly with increasing manganese content up to about 12% and then tend to level off, although small improvements normally continue up to about 13% Mn.

Fig. 5 Variation of properties with manganese content for austenitic manganese steel containing 1.15% C. Data are for castings weighing 3.6 to 4.5 kg (8 to 10 lb) and about 25 mm (1 in.) in section size that were water quenched from 1040 to 1095 °C (1900 to 2000 °F). Flow under impact is the total reduction in height sustained by a cylindrical specimen 25 mm (1 in.) in both diameter and length after absorbing 20 blows of 680 J (500 ft · lbf) each. Source: Abex Research Center

Silicon and Phosphorus. As noted in Table 1, silicon and phosphorus are present in all ASTM A 128 grades of austenitic manganese steel. Silicon is seldom added except for steelmaking purposes. Silicon content exceeding 1% is uncommon, because foundries do not like to have the silicon pyramid in melts containing returned scrap. A silicon content of 1 to 2% might be used to increase yield strength to a moderate degree, but other elements are preferred for this

effect. Loss of strength is abrupt above 2.2% Si, and Mn steel containing more than 2.3% Si may be worthless. On the other hand, silicon levels below 0.10% show decreased fluidity during casting.

The availability of low-phosphorus ferro-manganese since about 1960 has enabled steelmakers to reduce phosphorus levels in manganese steel to a large extent. The preferred practice is to hold the phosphorus content below 0.04% even though 0.07% is permitted by ASTM A 128. Levels above 0.06%, which formerly were prevalent, contribute to hot shortness and low elongation at very high temperatures and frequently are the cause of hot tears in castings and underbead cracking in weldments. It is particularly advantageous to keep phosphorus at the lowest possible level in the grades that are welded, and in manganese steel welding electrodes, and in heavy section castings.

Common Alloy Modifications. The most common alloying elements are chromium, molybdenum, and nickel (see Table 1). Added to the usual carbon level of about 1.15%, both chromium and molybdenum increase yield strength (Fig. 6) and flow resistance under impact.

Fig. 6 Effects of (a) chromium, (b) molybdenum, and (c) nickel contents on the tensile properties of cast manganese steel. Steel was cast in 25 mm (1 in.) diam test bars, reheated to 1095 °C (2000 °F), and water quenched. Source: Ref 6

Chromium additions are less expensive for a given increase, and chromium grades (ASTM A 128, grade C, for instance) are probably the most common modifications. ASTM A 128, grade B, often contains some chromium also. The 2% chromium addition in grade C does not significantly lower toughness in light sections. However, in heavier sections, its effect is similar to that of raising the carbon level; the result is a decrease in ductility due to an increase in the volume fraction of carbides in the microstructure. Chromium additions have been used up to 6% for some applications, sometimes in combination with copper, but these grades no longer receive much attention. Chromium enhances resistance to both atmospheric corrosion and abrasion, although the latter effect is not always consistent and depends on the individual application. It is also used up to 18% in low-carbon electrodes for welding manganese steel. Because of the stabilizing effect of chromium on iron carbide, higher heat-treatment (solutionizing) temperatures are often necessary prior to water quenching.

Molybdenum additions, usually 0.5 to 2%, are made to improve the toughness and resistance to cracking of castings in the as-cast condition and to raise the yield strength (and possibly toughness) of heavy-section castings in the solution-treated and quenched condition. These effects occur because molybdenum in manganese steel is distributed partly in solution in the austenite and partly in primary carbides formed during solidification of the steel. The molybdenum in solution effectively suppresses the formation of both embrittling carbide precipitates and pearlite, even when the austenite is exposed to temperatures above 275 °C (530 °F) during welding or in service. The molybdenum in primary carbides tends to change the morphology from continuous envelopes around austenite dendrites to a less harmful nodular form, especially when the molybdenum content exceeds 1.5%.

The 1% molybdenum grades (ASTM A 128, grade E-1, and AWS A5.13, grade EFeMn-B) are resistant to the reheating effect that limits the usefulness of the standard B-2, B-3, and B-4 grades. Grade E-1 is adapted to heavy-section castings used in roll and impact crushers that are frequently reheated during weld buildup and overlays.

Grade E-2, which contains about 2% Mo, may be given a special heat treatment to develop a structure of finely dispersed carbides in austenite. This heat treatment entails a partial grain refinement (U.S. Patent 1,975,746) by pearlitizing near 595 °C (1105 °F) for 12 h and water quenching from 980 °C (1800 °F). This type of microstructure has been found to enhance abrasion resistance in crusher applications. The tensile properties of specimens removed from worn cone crusher parts ranged from 440 to 485 MPa (64 to 70 ksi) in yield strength, 695 to 850 MPa (100 to 125 ksi) in tensile strength, and 15 to 25% in elongation.

The addition of molybdenum in amounts greater than 1% can increase the susceptibility of the manganese steel to incipient fusion during heat treatment. Incipient melting refers to a liquation phenomenon that occurs because of the presence of low-melting constituents in interdendritic areas, both within individual grains and along grain boundaries. This tendency is aggravated by higher P levels (>0.05%), higher pouring temperatures (which promote segregation in the casting), and higher carbon levels (>1.3%) in the steel.

As a further use, molybdenum is added to the lean manganese steel grade F partly to suppress embrittlement in both as-cast and heat-treated conditions.

Nickel, in amounts up to 4%, stabilizes the austenite because it remains in solid solution. It is particularly effective for suppressing precipitates of carbide platelets, which can form between about 300 to 550 °C (570 to 1020 °F). Therefore, the presence of nickel helps retain nonmagnetic qualities in the steel, especially in the decarburized surface layers. Nickel additions increase ductility, decrease yield strength slightly, and lower the abrasion resistance of manganese steel. Nickel is used primarily in the lower-carbon or weldable grades of cast manganese steel and in wrought manganese steel products (including welding electrodes). In wrought products, nickel is sometimes used in conjunction with molybdenum. The stability of nickel-containing manganese steels when reheated is shown in Table 2. Table 3 contains compositional and tensile data for nickel manganese steels used in naval applications.

(a) These grades are intended primarily for nonmagnetic applications and have minimum surface permeability of 1.2, measured with a go/no go low permeability, μ , indicator, as described in MIL-I-17214 and MIL-N-17387. The comparable casting specification, MIL-S-17249(Ships), includes only the standard 1.00 to 2.35% C grade.

(b) 0.2% offset

Manganese. ASTM A 128, grade F, has reduced manganese (6 to 8%) to make the austenite less stable, but this requires compensation with 1% Mo to gain acceptable properties. Work-hardening rates are reported to be higher than that of the standard 13% Mn grades, with some loss in toughness. This grade has been used in scoop lips, ball mill end liners, discharge grates, and grizzly screens for siliceous ore milling. One record indicates 45% longer life in ball mill discharge grates compared to pearlitic chromium-molybdenum steel used previously. Average properties reported were 415 MPa (60 ksi) yield strength, 585 MPa (85 ksi) tensile strength, and 12% elongation for carbon levels of 1.2 to 1.4%. ASTM A 128, grade F, is not adapted to heavy sections or to service involving temperatures above 315 °C (600 °F). It has poor weldability and should be avoided if a casting must be hardfaced or rebuilt.

Several other elements not listed in Table 1 (for example, vanadium, copper, titanium, and bismuth) are added to manganese steel for unique applications.

Vanadium is a strong carbide former, and its addition to manganese steels substantially increases yield strength, but with a corresponding decrease in ductility. Vanadium is used in precipitation-hardening manganese steels in amounts ranging from 0.5 to 2%. Because of the stability of vanadium carbonitrides, a higher solutionizing temperature 1120 to 1175 °C (2050 to 2150 °F) is recommended prior to aging (usually between 500 to 650 °C or 930 to 1200 °F). Yield

strengths of over 700 MPa (100 ksi) are obtainable depending on the level of ductility that can be tolerated for a given application. Tests of an age-hardened manganese-nickel-molybdenum-vanadium austenitic alloy demonstrated that the abrasion resistance of this steel is not as good as that of the standard grades (Ref 7).

Copper. Like nickel, copper in amounts of 1 to 5% has been used in austenitic manganese steels to stabilize the austenite. The effects of copper on mechanical properties have not been clearly established. Scattered reports indicate that it may have an embrittling effect, which may be due to the limited solubility of copper in austenite.

Bismuth. Other elements such as bismuth and titanium are also added to standard manganese steels. Bismuth was found to improve machinability, especially when coupled with higher manganese levels (>13%).

Titanium can reduce carbon in austenite by forming very stable carbides. The resulting properties may simulate those of a lower-carbon grade. Titanium may also somewhat neutralize the effect of excessive phosphorus; some European practice is apparently based on this idea. Microalloying additions (<0.1%) of titanium, vanadium, boron, zirconium, and nitrogen have been reported to promote grain refinement in manganese steels. The effect, however, is inconsistent. Higher levels of these elements can result in serious losses in ductility. Nitrogen in amounts greater than 0.20% can cause gas porosity in castings. An overall reduction in grain size lowers the susceptibility of the steel to hot tearing.

Sulfur. The sulfur content in manganese steels seldom influences its properties, because the scavenging effect of manganese operates to eliminate sulfur by fixing it in the form of innocuous, rounded, sulfide inclusions. The elongation of these inclusions in wrought steels may contribute to directional properties; in cast steels, such inclusions are harmless. However, it is best to keep sulfur as low as is practically possible to minimize the number of inclusions in the microstructure that would be potential sites for the nucleation of fatigue cracks in service.

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Higher Manganese Content Steels

Austenitic steels with a higher manganese content (>15%) have recently been developed for applications requiring low magnetic permeability, μ , low temperature (cryogenic) strength, and low-temperature toughness. These applications stem from the development of superconducting technologies used in transportation systems and nuclear fusion research and to meet the need for structural materials to store and transport liquefied gases.

Table 4 gives some typical chemical compositions of high-manganese austenitic steels. For low magnetic permeability, these alloys have a lower carbon content than the regular Hadfield steels. The corresponding loss in yield strength is

compensated for by alloying with vanadium, nitrogen, chromium, molybdenum, and titanium. Chromium also imparts corrosion resistance, as required in some cryogenic applications.

(a) At -196 °C (-321 °F).

The alloys are used in the heat-treated (solution-annealed and quenched) condition except for those that are age-hardenable. Wrought alloys are available in the hot-rolled condition. The microstructure is usually a mixture of γ (face-centered cubic, or fcc) austenite and ϵ (hexagonal close-packed, or hcp) martensite. Typical mechanical properties are included in Table 4. The alloys are characterized by good ductility and toughness, both especially desirable attributes in cryogenic applications. Further, the ductile-brittle transition is gradual, not abrupt. Because the stability of the austenite is composition dependent, a deformation-induced transformation can occur in service under certain conditions. This is usually undesirable because it is accompanied by a corresponding increase in magnetic permeability.

Additions of sulfur, calcium, and aluminum are made to enhance the machinability of these alloys where required. Because of their lower carbon content, most of these alloys are readily weldable by the shielded metal arc welding (SMAW), gas metal arc welding (GMAW), and electron beam welding (EBW) processes. The composition of the weld metal is similar to that of the base metal and tailored for low magnetic permeability. The phosphorus content is generally maintained below 0.02% to minimize the tendency for hot cracking.

Physical Properties. The coefficient of thermal expansion decreases with increasing manganese content and generally ranges from 8 to $17 \times 10^{-6}/^{\circ}\text{C}$ (4 to $9.5 \times 10^{-6}/^{\circ}\text{F}$). The electrical resistivity of a 0.7C-15Mn-1Ni alloy is reported to be about $710 \mu\Omega \cdot \text{mm}$. The thermal conductivity of the 32% Mn, 7% Cr alloy was determined to be $0.0314 \text{ cal}_{\text{T}}/\text{cm} \cdot \text{s} \cdot ^{\circ}\text{C}$ ($\sim 13 \text{ W/m} \cdot \text{K}$) at room temperature.

Another class of austenitic steels with high manganese additions has been developed for cryogenic and for marine applications with good resistance to cavitation corrosion. Potential applications also include those that require high-temperature corrosion resistance. These alloys have been viewed as economical substitutes for conventional austenitic stainless steels because they contain aluminum and manganese instead of chromium and nickel. Some examples of these steels are given in Table 5.

These alloys are generally of higher strength but lower ductility than conventional stainless steels such as type 304. Typical mechanical properties are also shown in Table 5. The microstructure in these alloys is a mixture of γ (fcc) austenite and ε (hcp) martensite, and in some cases (especially when the aluminum content exceeds about 5%) α (bcc) ferrite, too, and is obtained by a solution-annealing heat treatment. There is a tendency for an embrittling β -Mn phase to form in the high-manganese compositions during aging at elevated temperatures. The result is a significant decrease in ductility. The addition of aluminum to some extent suppresses the precipitation of this compound.

Fabrication. While these alloys require special precautions during melting due to their high aluminum contents, they are fairly easily hot worked and are usable in wrought form. Data on weldability is not readily available; it is suspected, however, that overall weldability is poor.

Oxidation. The oxidation resistance of these alloys is inferior to that of the chromium-containing grades of stainless steels because of the poor adhesion of aluminum oxide scale. This is especially evident under thermal cycling conditions.

Melt Practice

Austenitic manganese steels are most commonly produced in electric arc furnaces using a basic melting practice. Typical charge materials include carbon and manganese steel scrap, high-carbon ferromanganese, ferrosilicon, and silicon-manganese. Alloying elements such as chromium, molybdenum, and vanadium are usually added as ferroalloys, while elements such as nickel are used in a nearly pure metallic state. Deoxidation of the steel is accomplished with aluminum prior to pouring. In the case of most castings, the pouring temperature is regulated to less than 1470 °C (2680 °F) to prevent an excessively coarse grain size and minimize chemical segregation and other related casting defects. Sand castings are produced with olivine rather than silica sand to prevent mold-metal reaction. The grain size of wrought manganese steels is usually much lower than that of castings due to the recovery and recrystallization of the austenite grains during the hot rolling process. Further details of melting practice can be found in Ref 13.

As-Cast Properties

Although austenitic manganese steels in the as-cast condition are generally considered too brittle for normal use, Table 6 demonstrates that there are exceptions to this rule. Mechanical properties are listed for five grades of as-cast austenitic manganese steels of various thicknesses. These data indicate that lowering carbon content to less than 1.1% and/or adding about 1.0% Mo or about 3.5% Ni results in commercially acceptable as-cast ductilities in light and moderate section thicknesses. These data also apply to weld deposits, which are normally left in the as-deposited condition and therefore are essentially equivalent to material in the as-cast condition.

(a) Properties converted from transverse bend tests on 6.4×13 mm ($\frac{1}{4} \times \frac{1}{2}$ in.) bars cut from castings and broken by center loading across 25 mm (1 in.) span.

Adjustments in composition that limit carbide embrittlement and austenite transformation reduce or eliminate cracking of manganese steel castings during cooling in the molds or reheating for solution treatment. The steel is generally poured at temperatures just high enough to avoid misruns in the castings and excessive skulling of the metal in the ladle. This practice helps ensure rapid solidification of the metal in the molds, which in turn helps prevent an excessively coarse grain size. The final microstructure in most castings is not fully austenitic, but contains carbide precipitates and pearlite in an austenitic matrix.

Commercial use of castings in the as-cast condition results in cost and energy savings and eliminates the problems of decarburization of thin castings during solution treatment and warpage during water quenching. Full ductility or toughness is not required in certain applications of manganese steels. For example, as-cast manganese steels have been used successfully for pans on pan conveyors and for other light-section applications where solution-treated and water-quenched castings were prone to severe warpage.

Of the steels listed in Table 6, the 6Mn-1Mo grades are most susceptible to strain-induced martensite embrittlement because of their low manganese levels. However, even these grades can be used in applications for which 1% elongation (either determined in a tensile test or estimated from a transverse bend test) is considered adequate ductility. For example, the as-cast 6Mn-1Mo grade containing 0.8 to 1.0% C has been used successfully in grinding mill liners.

Heavy Sections. As section thickness increases, the rate at which castings cool in sand molds decreases. This increases the opportunity for embrittlement by carbide precipitation. Shapes that tend to develop high residual stresses, such as

cylinders and cones, can be particularly affected. These stresses most probably result from volume changes accompanying the carbide precipitation and austenite transformation that occur during the normal cooling of castings.

Figure 7 shows the volume changes that occur during the isothermal decomposition of a 1.25C-12.8Mn steel at temperatures between 850 and 500 °C (1560 and 930 °F), the principal range within which embrittlement occurs when a casting is cooled in its mold or reheated for reaustenitization. Between 850 and about 705 °C (1560 and 1300 °F), only carbides are precipitated, primarily as envelopes around austenite grains and as lamellar-type patches within grains. The lamellar carbide patches have the appearance of coarse pearlite, but actually they are carbide plates in austenite. Below 705 °C (1300 °F), and particularly between 650 and 550 °C (1200 and 1020 °F), pearlite nodules, nucleated by previously precipitated carbides, grow at a relatively rapid rate.

Fig. 7 Change in length of an austenitic 1.25C-12.8Mn steel during isothermal transformation. Source: Ref 14

Transgranular acicular carbides also tend to precipitate below about 600 °C (1110 °F), especially in austenite containing more than about 1.1% C. This precipitation can continue down to about 300 °C (570 °F) in a 1.2C-12Mn steel. It may be followed by the transformation of some of the carbon-depleted austenite to martensite as the ambient temperature is approached.

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Heat Treatment

Heat treatment strengthens austenitic manganese steel so that it can be used safely and reliably in a wide variety of engineering applications. Solution annealing and quenching, the standard treatment that produces normal tensile properties and the desired toughness, involves austenitizing followed quickly by water quenching. Figure 8 shows the microstructures of a 76 mm (3 in.) section of austenitic manganese steel in the as-cast condition and after solution

annealing and quenching. Variations of this treatment can be used to enhance specific desired properties such as yield strength and abrasion resistance. Usually, a fully austenitic structure, essentially free of carbides and reasonably homogeneous with respect to carbon and manganese, is desired in the as-quenched condition, although this is not always attainable in heavy sections or in steels containing carbide-forming elements such as chromium, molybdenum, vanadium, and titanium. If carbides exist in the as-quenched structure, it is desirable for them to be present as relatively innocuous particles or nodules within the austenite grains rather than as continuous envelopes at grain boundaries.

Fig. 8 Typical structures of as-cast and heat-treated ASTM A 128, grade B-3, manganese steel. Top: As-cast material 76 mm (3 in.) thick, with large carbides along grain boundaries. Bottom: 76 mm (3 in.) thick material heated to 1120 °C (2050 °F) and water quenched. Both samples etched in $2\frac{1}{2}$ % nital, rinsed in methanol, and reetched in 15% HCl. Both 500×.

Procedures. Full solution of carbides requires a solution-treating temperature that exceeds A_{cm} by about 30 to 50 °C (50 to 90 °F). Soaking for 1 to 2 h at temperature is usually adequate. Although it might appear that temperatures above 1095 °C (2000 °F) would permit use of 1.4 to 1.5% C, three factors discourage the use of very high temperatures:

- Incipient melting occurs in areas of carbon and phosphorus segregation
- Scaling and decarburization become excessive
- Commercial quenching rates are limited in their ability to retain high carbon concentrations in solution

The commercial heat treatment of manganese steel castings normally involves heating slowly to 1010 to 1090 °C (1850 to 2000 °F), soaking for 1 to 2 h per 25 mm (1 in.) of thickness at temperature, and then quenching in agitated water. There is some tendency for the austenite grains to grow during soaking, especially in wrought manganese steels, although final austenite grain size in castings is largely determined by pouring temperature and solidification rate.

For grade E-2 manganese steel (see Table 1), a modified heat treatment is often specified or recommended. This treatment consists of heating castings to about 595 °C (1100 °F) and soaking them 8 to 12 h at temperature, which causes substantial amounts of pearlite to form in the structure. The castings are then further heated to about 980 °C (1800 °F) to reaustenitize the structure. This step converts the pearlitic areas to fine-grain austenite containing a dispersion of small carbide particles, which remain undissolved as long as the austenitizing temperature does not exceed about 1010 °C (1850

°F). Quenching then results in a dispersion-hardened austenite, which is characterized by higher yield strength, higher hardness, and lower ductility than would be obtained if the same steel were given a full solution treatment at a higher austenitizing temperature. This dispersion-hardening heat treatment permits a relatively high carbon content which in turn can improve abrasion resistance.

Precautions. Speed of quenching is important, but it is difficult to increase beyond the rate of heat transfer from a hot surface to agitated water or beyond the rate fixed by the thermal conductivity of the metal. As a result, heavy-section castings have lower mechanical properties at the center than do thinner castings. Figure 9 shows the cooling rates that can be expected when metal plates of four different thicknesses are quenched in water. Table 7 lists average properties observed in castings of 1.11C-12.7Mn-0.5Si-0.043P steel water quenched from about 980 °C (1800 °F), which cooled the castings at the rates shown in Fig. 9.

Fig. 9 Cooling curves for austenitic manganese steel of various thicknesses. Cooling curves are approximately equivalent to those for plate of the thicknesses indicated. Source: Ref 3

Residual stresses from quenching, coupled with the lower properties of heavy sections, establish the usual maximum thickness of commercial castings at about 127 to 152 mm (5 to 6 in.), although castings with sections up to 406 mm (16 in.) thick have been produced.

There have been reports of two-step quenching cycles being used to decrease the overall thermal gradient and thereby to reduce the residual stresses associated with heat-treatment operations. However, this is not common practice in the industry and is probably restricted to specific products. Residual stresses in manganese steels are not a critical issue because of their inherent toughness.

The relatively high austenitizing temperature leads to marked surface decarburization by furnace gases and to some loss of manganese. Surface decarburization may extend as much as 3.2 mm ($\frac{1}{8}$ in.) below the casting surface. Thus, the skin may be partly martensitic at times and usually exhibits properties less desirable than those of the underlying metal. This characteristic is not significant in parts subjected to abrasion, such as those used in crushing or grinding, because in these applications the skin is removed by normal wear. Tensile deformation in service sometimes produces numerous cracks in this inferior skin, which terminate where they reach the tough austenite of normal composition except along grain boundaries, which contain mostly continuous carbides (for example, due to slack quenching during heat treatment). Service performance is not seriously affected except under critical fatigue conditions or in very light sections; in such instances, premature failure may result. If considered necessary, a proprietary grade (equivalent to ASTM grade B-2 to which 6% Cr has been added) that is less prone to surface decarburization can be specified. Under certain conditions, sections such as wrought sheets may be protected with inert or reducing gas atmospheres, or with covers, metal envelopes, or organic or inorganic coatings, to minimize decarburization.

For applications that require nonmagnetic properties, alteration of the skin by furnace gases requires attention. If the affected skin, which is usually magnetic, is quite shallow, it may be possible to remove it by pickling. In heavy sections, where skin thickness may approach 3.2 mm ($\frac{1}{8}$ in.), the altered layer should be removed by grinding if a surface permeability below 1.3 is required. Metallographic procedures and microstructural interpretations are discussed in detail in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Mechanical Properties After Heat Treatment

As the section size of manganese steel increases, tensile strength and ductility decrease substantially in specimens cut from heat-treated castings. This occurs because, except under specially controlled conditions, heavy sections do not solidify in the mold fast enough to prevent coarse grain size, a condition that is not altered by heat treatment. As shown in Table 7, fine-grain specimens may exhibit tensile strength and elongation as much as 30% greater than those of coarse-grain specimens. It is important to note that care should be taken during tensile tests to ensure that the gage section in cast specimens contains an adequate number of grains as required by the ASTM-E8 standard.

Grain size also is the chief reason for the difference between cast and wrought manganese steels (the latter are usually of fine grain size). For cast grade B-2, the standard deviations for tensile strength and elongation are about 69 MPa (10 ksi) and 9%, respectively. The midrange values of 825 MPa (120 ksi) and 40% apply to sound, medium-grain cast specimens that have been properly heat treated. The scatter bands for this grade extend from 620 to 1035 MPa (90 to 150 ksi) for tensile strength and from 13 to 67% for elongation.

Mechanical properties vary with section size. Tensile strength, tensile elongation, reduction in area, and impact strength are substantially lower in 102 mm (4 in.) thick sections than in 25 mm (1 in.) thick sections. Because section thicknesses of production castings are often from 102 to 152 mm (4 to 6 in.), this factor is an important consideration for proper grade specification.

Notched-bar impact test values can be exceptionally high. Charpy test specimens are sometimes bent and dragged through the machine rather than being fractured. Occasionally, observed values are biased because of the incorrect preparation of specimens. Notches should be cut by precision grinding to minimize work hardening at the apex of the notch.

Austenitic manganese steel remains tough at subzero temperatures above the M_s temperature. The steel is apparently immune to hydrogen embrittlement, although embrittlement has been produced in steels with low carbon content ($< \sim 0.02\%$) and high manganese content. There is a gradual decrease in impact strength with decreasing temperature. The transition temperature is not well defined because there is no sharp inflection in the impact strength-temperature curve down to temperatures as low as -85°C (-120°F). At a given temperature and section size, nickel and manganese additions are usually beneficial for enhancing impact strength, while higher carbon and chromium levels are not.

Resistance to crack propagation is high and is associated with very sluggish progressive failures. Because of this, any fatigue cracks that develop might be detected, and the affected part or parts removed from service before complete failure occurs, a capability that is a distinct advantage in railway track work. The fatigue limit of austenitic manganese steel has been reported as 270 MPa (39 ksi).

Yield strength and hardness vary only slightly with section size. The hardness of most grades is about 200 HB after solution annealing and quenching, but this value has little significance for estimating machinability or wear resistance. Hardness increases so rapidly because of work hardening during machining or while in service that austenitic manganese steels must be evaluated on some basis other than hardness.

The true tensile characteristics of manganese steel are better revealed by the stress-strain curves in Fig. 10, which compare manganese steel with gray iron and with a heat-treated, high-strength, low-alloy steel of about the same nominal tensile strength. The low yield strength is significant and may prevent the selection of this alloy where slight or moderate deformation is undesirable, unless the usefulness of the parts in question can be restored by grinding. However, if deformation is immaterial, the low yield values may be considered temporary, that is, deformation will produce a new, higher yield strength corresponding to the amount of strain that is absorbed locally.

Bend tests are often used as a qualitative indication of ductility in castings. A description of the bend test specimen and testing procedure is given in ASTM A 128 as a supplementary requirement. Typically, a separate test specimen is poured from the same heat and is heat treated with the batch of castings. This specimen is then tested by cold bending around a 25 mm (1 in.) diam mandrel without any further machining or grinding, except that required to remove surface decarburization. The ductility is judged to be acceptable in most cases if the specimen can be bent through an angle of 150° without breaking into two pieces.

Work Hardening

The approximate ranges of tensile properties produced in constructional alloy steels by heat treatment are developed in austenitic manganese steels by deformation-induced work hardening. In a tension test, yielding signifies the beginning of work hardening, and elongation is associated with its progress. Little or no necking occurs because work hardening is greatest at the point of greatest deformation. The increase in strength due to cold work stops further elongation, and deformation then occurs elsewhere in the gage section. This type of behavior is often compared to that exhibited by transformation-induced plasticity (TRIP) steels. Elongation thus occurs uniformly and without flow stress saturation, until failure.

A 1988 investigation (Ref 15) showed that fracture occurs because of a combination of microvoid coalescence (without shear localization) and surface cracking within regions of localized plastic flow. The nucleation of both voids and surface cracks was observed to be a function of carbides and nonmetallic inclusions in the steel, to some extent.

Plastic deformation is accompanied by the development of texture (Ref 16.) X-ray diffraction studies have shown this texture to be [111] in tension and [110] in compression, similar to the behavior of 70-30 brass. Also, work-hardening rates tend to be higher in compression than in tension.

The mechanism of work hardening has been the subject of numerous investigations (Ref 17, 18, 19, 20). Various mechanisms have been found to contribute to work hardening, depending on factors such as alloy composition (stacking fault energy, strain rate sensitivity), temperature, and strain rate. These mechanisms include twinning or pseudotwinning (Ref 16, 17), stacking fault formation (Ref 18), and dynamic strain aging (Ref 19, 20). However, it is well established that a deformation-induced transformation from austenite to α martensite (bcc) does not occur in ordinary Hadfield steels. The role of such a transformation in work hardening is more significant only at lower carbon and manganese levels.

On a macroscopic scale, the work-hardening rate has been observed to increase with increasing carbon content and decreasing grain size (Ref 21). Work-hardening rates of 1500 to 2500 MPa (218 to 363 ksi) have been measured in austenitic manganese steels at nominal strain rates of 10^{-4} /S at room temperature.

Determination of Work-Hardening Rate. The work-hardening rate is usually determined from ordinary tensile or compression tests as the slope of the true stress-true strain curve, which is mostly linear in the plastic region.

One other measure of the tendency of austenitic manganese steels to work harden is based on a determination of the so-called Meyer index or exponent. The technique employs a 10 mm diam Brinell ball indenter and a series of loads. The test loads are plotted against the diameters of the corresponding indentations on logarithmic scales. The result is expected to be a straight line that fit the equation:

$$P = A \cdot d^n \quad (\text{Eq 1})$$

where P represents the applied load; d , the diameter of the indentation; A , a constant; and n , a measure of the tendency of the metal to strain harden (also called the Meyer index or exponent). The Meyer index of a variety of austenitic manganese and stainless steels has been determined to be in the range of 2.17 to 2.60 (Ref 4).

Manganese steels are unequalled in their ability to work harden, exceeding even the metastable austenitic stainless steels in this feature. For example, a standard grade of manganese steel containing 1.0 to 1.4% C and 10 to 14% Mn can work harden from an initial level of 220 HV to a maximum of more than 900 HV. After extended service, the hardness at the wearing surfaces of railway frogs typically ranges from 495 to 535 HB. Maximum attainable hardness depends on many factors, including specified composition, service limitations, method of work hardening and preservice hardening procedures. It appears that rubbing under heavy pressure can produce higher values of maximum attainable hardness than can be produced by simple impact.

Service Limitations. In some cases, abrasion may remove surface metal before it can attain maximum hardness. In other instances, work hardening raises the elastic limit to the point that succeeding impact blows cannot cause more plastic flow and thus merely bounce off. However, if a rotating tool is applied with enough force and does not cut, accentuated work hardening can be expected. This is a common occurrence during drilling. A sharp twist drill of superior steel can drill 13% Mn steel provided a deep enough cut is taken, but cutting ceases if the drill becomes dull. When this happens, it is frequently futile to continue drilling, even with a sharp drill, because the bottom of the hole has become so hard that the cutting edge cannot penetrate it.

The low yield strength of manganese steel is sometimes a disadvantage in service. For example, plastic deformation due to wheel impact, as in railway frogs and crossings, increases yield strength to levels more resistant to flow, but the associated changes in dimensions are undesirable. With time, low spots develop at critically pounded locations, eventually requiring rebuilding with weld deposits. This problem is alleviated to some degree by hardening the running surface prior to in-service installation.

Low yield strength can also be a disadvantage when manganese steel is used in light armor and similar applications. Because much energy is absorbed during work hardening, manganese steel sheet is an effective light armor against slow-moving projectiles. However, manganese steel is relatively ineffective against high-velocity projectiles that shear through the armor with little accompanying deformation. One reason for this may be the negative strain rate sensitivity behavior exhibited by ordinary Hadfield steels. Heat-treated (quenched and tempered) alloy steels of higher yield strength are preferred for armor against high-velocity projectiles. However, most of the impact blows encountered in industrial service are of low velocity, and for this service, manganese steel is acceptable. It is the preferred choice for applications requiring high impact resistance, toughness, and absorption of energy.

Work-Hardening Methods. Work hardening is usually induced by impact, as from hammer blows. Light blows, even if they are of high velocity, cause shallow deformation with only superficial hardening even though the resulting surface hardness is ordinarily high. Heavy impact produces deeper hardening, usually with lower values of surface hardness. The course of flow under impact and the associated increase in hardness are shown in Fig. 11, which compares a standard 12% Mn steel with an air-hardening chromium-nickel-molybdenum alloy steel. Less well known is the fact that abrasion itself can produce work hardening.

Fig. 11 Plastic flow (top) and work hardening (bottom) of a manganese steel and an air-hardening steel under repeated impact. Specimens 25 mm (1 in.) in both diameter and length were struck repeatedly on one end by blows with an impact energy of 680 J (500 ft · lbf). Composition and heat treatment of the manganese steel were 1.17C-12.8Mn-0.46Si, water quenched from 1010 °C (1850 °F). Composition and heat treatment of the air-hardening steel were 0.74C-0.88Mn-0.30Si-0.75Ni-1.40Cr-0.38Mo; air cooled from 900 °C (1650 °F), reheated to 705 °C (1300 °F), and air cooled. Source: Ref 3

Explosion hardening was developed as a substitute for hammer or press hardening to achieve hardening with less deformation. Pentaerythritol tetranitrate (3.1 mg/mm², or 0.0044 lb/in.²) in the form of plastic explosive sheet 2.11 mm (0.083 in.) thick or mixtures of ammonium nitrate and trinitrotoluene (TNT) are cemented to the surface of the steel and detonated. Usually, three explosions are required to attain the desired hardness in railway track work. More explosions do not significantly change the pattern of hardening, but increase the possibility of cracking instead. The use of plastic explosive permits the hardening of areas such as track work flangeways and unsupported sections that cannot be hammered satisfactorily. Figure 12 compares the depth and intensity of hardening from three different explosion treatments and from one hammer peening operation applied to railway track work. Explosion hardening is now considered a satisfactory but expensive substitute for the hammer or press hardening of manganese steel trackwork castings.

Fig. 12 Hardening patterns in manganese steel railway crossings. Measurements were made on sections taken 19 mm ($\frac{3}{4}$ in.) from the flangeway on each sample crossing. Source: Ref 3

Explosion treatment has also been applied to parts that are to be subjected to abrasive wear. Initial reports were favorable, but have been reversed by subsequent experience; there is no solid evidence that explosion hardening is advantageous for service involving grinding or gouging abrasion.

Explosion hardening is accompanied by insignificant deformation in spite of the fact that work hardening is usually associated with plastic flow and deformation. Studies have centered on the premise that a different hardening mechanism, other than twinning, is involved in explosion hardening.

The addition of alloying elements such as vanadium, chromium, silicon, and molybdenum is also an effective means of raising yield strength, but vanadium, silicon, and chromium reduce ductility. The relative effects of alloying and of prehardening by deformation are compared in Fig. 13.

Fig. 13 Flow under repeated impact for several manganese steels and for rail steel at different hardnesses. Specimens 25 mm (1 in.) in both diameter and length were struck repeatedly by blows with an impact energy of 680 J (500 ft · lbf). Source: Ref 3

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Reheating

Before manganese steel parts are reheated in the field, the effects of such reheating must be seriously considered. Unlike ordinary structural steels, which become softer and more ductile when reheated, manganese steels suffer reduced ductility when reheated enough to induce carbide precipitation or some transformation of the austensite. Figure 14 shows the microstructural effects of such heating. As a general rule, manganese steels should never be heated above 260 °C (500 °F), either intentionally or accidentally, unless such heating can be followed by standard solution annealing and quenching.

Fig. 14 Structure of a typical reheated manganese steel. ASTM A 128, grade B-3, steel annealed at 1120 °C (2050 °F), water quenched, and reheated above 315 °C (600 °F). Structure is austenite with extensive carbide precipitation along grain boundaries and within grains. Specimen was etched in 2.5% nital, rinsed in ethanol, and reetched in 15% HCl. 500×

Time, temperature, and composition are variables in the embrittlement process. At lower temperatures, embrittlement takes longer to develop. The time-temperature relationship in 13Mn-1.2C-0.5Si steel is shown in Fig. 15, which presents data based on metallographic examination for structural changes that indicate the beginning of embrittlement. At 260 °C (500 °F), transformation requires more than 1000 h; reheating to as high a 425 °C (800 °F), even with close control of temperature, may be done for no longer than 1 h if transformation is to be avoided. Figure 16 shows the effect of composition on the magnitude of embrittlement.

Fig. 15 Time-temperature relationship for embrittlement of 13Mn-1.2C-0.5Si steel. Prior to reheating, the alloy was annealed 2 h at 1095 °C (2000 °F) and water quenched. Source: Ref 3

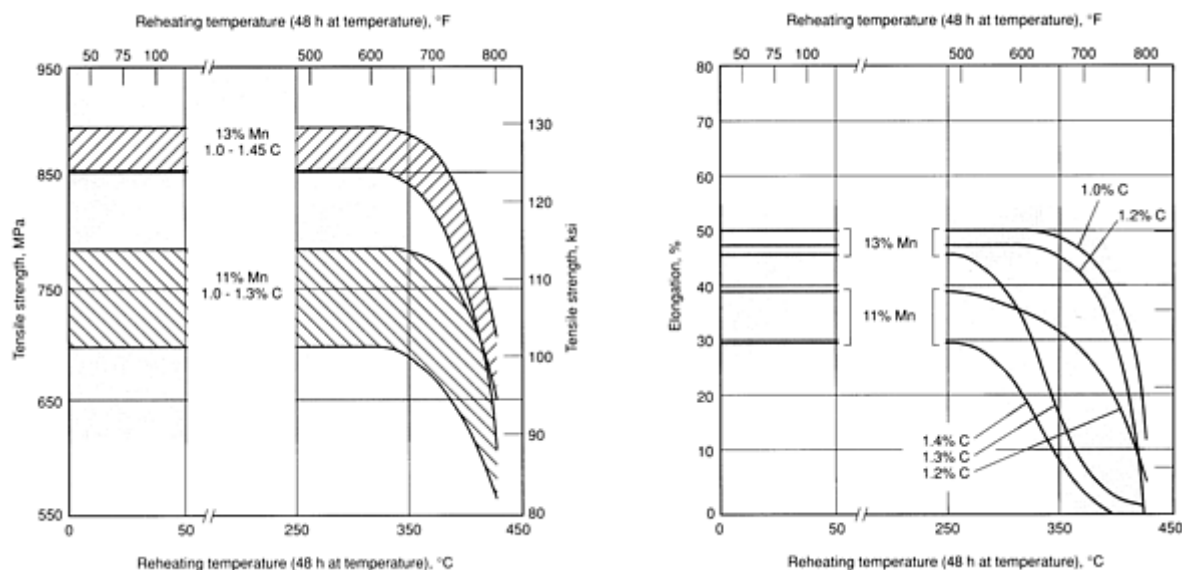

Fig. 16 Embrittlement from reheating manganese steel. Cast bars 25 mm (1 in.) in diameter were reheated 48 h at the temperatures indicated after solution annealing and quenching. Source: Ref 3

Because large castings are sometimes mounted with backings of molten lead or zinc, the temperature of such castings should be carefully controlled during reheating. The time-temperature relationship should also be given due consideration for parts that must be welded.

When 12 to 14% Mn steels are to be heated above about 290 °C (550 °F) during service or welding, it is recommended that the carbon content be held below 1.0%, which will suppress embrittlement for at least 48 h at temperatures up to 370 °C (700 °F). The addition of 1.0% Mo will suppress embrittlement completely at temperatures up to 480 °C (900 °F) and will partly suppress it at temperatures of 480 to 595 °C (900 to 1100 °F). If the carbon content is held below about 0.9%, the addition of 3.5% Ni will completely suppress embrittlement up to 480 °C (900 °F) and will partly suppress it above this temperature. These rules can be expected to apply during heating periods of up to 100 h. For periods of 1000 h or more, limiting temperatures are substantially lower. It should be noted that localized carbon contents can still exceed 1.0% because of chemical segregation. Hence, these guidelines should be used with caution.

Table 2 lists properties of three 1.0% C manganese steels that were reheated for periods of up to 10 h at temperatures up to 595 °C (1100 °F). At 370 °C (700 °F), none of the three steels was embrittled; in fact, there were indications that the treatment had effected slight improvements in ductility. At 480 °C (900 °F), the plain manganese steel and the manganese-nickel steel were embrittled, but there was little change in the properties of the manganese-molybdenum steel. At 595 °C (1100 °F), all three steels were embrittled, but the plain manganese steel was more severely affected than the others.

Embrittlement, as revealed by microstructural investigation, was caused by the formation of acicular carbide and pearlite in the austenite grains of the plain manganese steel, by carbide nodules surrounded by pearlite within the austenite grains of the manganese-molybdenum steel, and by an envelope of proeutectoid cementite around each grain of the manganese-nickel steel. If the carbon content in the manganese-nickel steel had been lower, the steel might have been substantially less susceptible to embrittlement. In another investigation, a 0.9C-14.3Mn-1.75Si-3.4Ni steel did not become significantly embrittled when it was heated for $1\frac{1}{2}$ h at 480 °C (900 °F), and its ductility was reduced by only 17 to 20% when it was heated for $1\frac{1}{2}$ h at 595 to 760 °C (1100 to 1400 °F).

Austenitic Manganese Steels

Revised by D.K. Subramanyam,* Ergenics Inc.; A.E. Swansiger, ABC Rail Corporation; and H.S. Avery, Consultant

Wear Resistance

Compared to most other abrasion-resistant ferrous alloys, manganese steels are superior in toughness and moderate in cost, and it is primarily for these reasons that they are selected for a wide variety of abrasive applications. They are usually less resistant to abrasion than are martensitic white irons or martensitic high-carbon steels, but are often more resistant than pearlitic white irons or pearlitic steels.

The type of wear that is sustained has a major influence on the performance of manganese steels. They have excellent resistance to metal-to-metal wear, as in sheave wheels, crane wheels, and car wheels; good resistance to gouging abrasion, as in equipment for handling or crushing rock; intermediate resistance to high-stress (grinding) abrasion, as in ball mill and rod mill liners; and relatively low resistance to low-stress abrasion, as in equipment for handling loose sand or sand slurries.

Metal-to-Metal Contact. In applications involving metal-to-metal contact, the work hardening of manganese steel is a distinct advantage because it decreases the coefficient of friction and confers resistance to galling if temperatures are not excessive. Compressive loads, rather than impact, provide the deformation required, producing a smooth, hard surface that has good resistance to wear but that does not abrade the contacting part. Sheaves, wear plates, and castings for railway track work are common applications of this type. Manganese steel also has been used in some water-lubricated bearings.

Railway center plates, which are the bearing surfaces where trucks swivel under freight cars, provide a good example of the merit of manganese steel for metal-to-metal frictional wear. Initially lubricated, these plates soon are operating dry and are accessible to airborne grit. When plates are made of carbon steel, the mating surfaces become rough from galling (adhesive wear); the increased friction prevents easy motion, the trucks do not swivel properly on curves, and the lateral pressure is so accentuated that early wheel flange wear is induced. Poor swiveling may accentuate thrust loads at the ends of wheel bearings, generating excessive frictional heat, and center plates and mating bowls on trucks may wear severely. Many years ago, the substitution of 13% Mn steel center plates on heavily loaded ore cars demonstrated their superiority. More recently, various service tests have demonstrated that manganese steel not only wears less than carbon steel, but also develops a low-friction polished surface. The advantages of manganese steel center plates are most evident for cars that are very heavily loaded.

Manganese steel wear plates in a blooming mill housing were in good condition after 16 years, whereas carbon steel plates required replacement every 2 years. Manganese steel wear plates on ore bridge haulage drums were reported to be as good as new after $5\frac{1}{2}$ years of service, whereas ordinary cast steel plates wore out in about 3 years. Manganese steel sheave wheels are expected to last about four times as long as cast carbon steel wheels and they do not groove and cause excessive rope wear, as do wheels made of alloys that do not work harden. In steel mill applications, welded manganese steel overlays on large mill-coupling boxes, pinions, spindles, and other items working under heavy impact loads perform satisfactorily.

Abrasion. The concept that manganese steel has poor wear resistance unless it has been work hardened is not a valid generalization. The misunderstanding has probably developed because, where significant impact and attendant work hardening are present, 12% Mn steel is so clearly superior to other metals that its performance is attributed to surface hardening. However, controlled abrasion tests have indicated that there are circumstances under which the abrasion resistance of austenitic manganese steel is modified little by preservice work hardening, and other circumstances under which this steel will outwear harder pearlitic white cast irons without work hardening.

In applications that involve heavy blows or high compressive and structural stresses, the very hard and abrasion-resistant martensitic cast irons may wear more slowly than manganese steel. However, these irons usually fail by early fracture

with a considerable portion of the original cross section unworn, whereas manganese steel may become almost paper thin before fracturing.

Pearlitic white cast iron, which has a hardness of about 400 to 450 HB, is equally brittle but less resistant to wear. Comparative tests on log washer lugs indicated that manganese steel was about 25% worn out with no breakage, whereas in the same period white iron lugs wore to the point of uselessness with 14% breakage. In clay crusher rolls, manganese steel lasted two to three times as long as white or chilled iron. In grinding barrel liners, cast irons lasted 2 to 3 years compared to 10 years for manganese steel. Part of the superiority of manganese steel over white cast iron is attributed to greater freedom from breakage and spalling, but some is probably due to better intrinsic wear resistance.

Manganese steel chain, with endless links cast in interlocking molds, also provides resistance to wear, lasting three to nine times as long as heat-treated steel chain in certain applications. Manganese steel is valuable in conveyors as well as in dragline chain subjected to abrasion and used for carrying heavy loads.

Manganese steel is not satisfactorily resistant to wear by a stream of airborne abrasive particles (impingement erosion), such as in sandblasting or gritblasting equipment, and consequently should not be selected for such service.

Abrasion Testing. A number of laboratory abrasion and wear testing procedures have been developed to simulate a variety of applications with differing degrees of severity. These include a jaw crusher test for gouging abrasion resistance (ASTM G 81), a dry-sand/rubber wheel low-stress abrasion test (ASTM G 65), testing for slurry abrasiveness (ASTM G 75), and tests for galling resistance (ASTM G 83 and G 98). Other procedures such as a wet-sand/rubber wheel low-stress abrasion test and a pin-on-disk high-stress abrasion test^{**} are also nearing standardization at this writing.

Table 8 Relative resistance of various materials to high-stress grinding abrasion by wet quartz sand

Material	Hardness, HB	Abrasion factor ^(a)
Cemented tungsten carbide	. . .	0.17
Martensitic Ni-Hard cast iron	550-750	0.25-0.60
Martensitic 4150 steel	715	0.60±
Bainitic 4150 steel	512	0.75±
Austenitic 12% Mn steel	200	0.75-0.85
Pearlitic 0.85% C steel	220-350	0.75-0.85
Alloyed white cast irons	400-600	0.70-1.00
Unalloyed white cast irons	400±	0.90-1.00
1020 steel (standard)	107	1.00
Gray cast irons	200±	1.00-1.50

Ferritic ingot iron	90	1.40

- (a) Particle size of abrasive, 50 to 55 AFS grain fineness number, compressive stress on specimen about 370 KPa (54 psi), as determined at the Abex Research Center. Ratio of weight loss of sample to weight loss of the standard material, 1020 steel. High factors indicate poor wear resistance.

Many variations of the pin test are used to measure wear resistance. One test method utilizes abrasive paper or cloth mounted on a revolving disk, the abraded flat tip of a small pin moving in a spiral path. The Climax lab used a milling machine platen with a revolving pin taking a zig-zag path. The Bureau of Mines and some workers in Australia have the pin making a spiral path against garnet paper or cloth fastened to a large revolving drum. The common feature of these test methods is a small pin specimen, but the pins are subjected to a variety of conditions: normal load, tangential force, abrasive type, abrasive grain size, abrasive angularity or roundness, temperature, abrasive concentration, and so on.

The rankings of a number of metals in various abrasion tests are given in Tables 8, 9, and 10. A considerable amount of test data on abrasion resistance of a wide variety of austenitic manganese steels has been accumulated (see the article "Wear Resistance" in Volume 1 of the 9th edition of *Metals Handbook*).

Table 9 Relative wear rates of various materials tested as 127 mm (5 in.) grinding balls in a ball mill

Material	Nominal composition, %					Hardness, HB ^(a)	Relative wear rate ^(b)	Order of toughness ^(c)
	C	Mn	Cr	Mo	Ni			
Martensitic Cr-Mo white iron	2.8	1.0	15.0	2.0	...	740	89	7
Martensitic high-chromium white iron	2.7	1.0	26.0	705	98	8
Martensitic high-carbon Cr-Mo steel (type 3)	1.0	0.8	6.0	1.0	...	615	100	6
Martensitic high-carbon Cr-Mo Steel (type 2)	0.7	0.7	2.0	0.4	...	560	110	5
Martensitic Ni-Cr white iron	3.2	0.8	2.0	...	4.0	650	112	9
Austenitic 6Mn-1Mo steel	0.9	6.0	...	1.0	...	490	114	3

- (a) Hardnesses are converted from the average of HRC readings on the worn surfaces of the balls. Hardnesses below the cold-worked surface are normally lower than those given.
- (b) Relative wear rates are based on a nominally assigned factor of 100 for the high-carbon martensitic steel (type 3). Factors greater than 100 indicate higher rates of wear, and factors less than 100 indicate proportionately lower rates of wear.
- (c) Order of toughness listed here is a qualitative value, based partly on results of laboratory tests and partly on the basis of resistance to breakage and spalling that the respective materials have shown in service.

Table 10 Relative gouging abrasion resistance in the ASTM G 81 jaw crusher test

Alloy type ^(a)	Laboratory A		Laboratory B	
	Wear ratio ^(b)	Hardness, HB	Wear ratio ^(b)	Hardness, HB
T-1 type A steel (0.19% C), WQ and T (650 °C, or 1200 °F)	0.983	269	1.085±0.013	260
	1.024	269	1.085±0.013	260
	1.022	269	1.085±0.013	260
	1.027	269	1.085±0.013	260
Austenitic 12% Mn steel, WQ	0.279	...	0.279	199
Austenitic 12Mn-2Cr steel, WQ	0.247	...	0.249	232
4340 steel, OQ and T (650 °C, or 1200 °F)	0.788	321	0.716	340
4340 steel, OQ and T (205 °C, or 400 °F)	0.262	555	0.232	520
27% Cr white iron, AC and T (230 °C, or 445 °F)	0.166	653	0.144	662
15 Cr-3Mo white iron, AC and T (230 °C, or 445 °F)	0.088	750+	0.076	816
20Cr-3Mo white iron, hardfacing alloy	0.201	(51.7 HRC)	0.170	...
0.30% C cast low-alloy steel, WQ and T (205 °C, or 400 °F)	0.286	514	0.288	499

(a) WQ, water quenched; T, tempered; OQ, oil quenched; AC, air-cooled.

(b) Ratio of weight loss of sample to weight loss of the standard material, martensitic T-1 steel plate. High values indicate poor wear resistance

There is little need for laboratory tests in the case of well authenticated applications, but such tests can be useful to judging suitability for new applications. The usefulness of these tests is dependent on their precision and reliability (versus statistical standards) and their validity as determined from comparisons with service tests. Crusher tests are slow and expensive, motivating attempts to correlate more convenient procedures, such as a pin on abrasive paper or cloth. Table 11 compares the abrasion resistance (abrasion factors) of a number of alloys as determined by four separate laboratory testing procedures.

Table 11 Comparison of several abrasion tests involving manganese steel

Abrasion factors relative to A 514 steel. Data from U.S. Bureau of Mines Research Center

Material	Hardness, HB	Abrasion tests			
		Slurry	Dry sand/ rubber wheel	Pin-on-drum test	Jaw crusher
A 514 steel, 0.19% C	269	1.00	1.00	1.00	1.00

Slurry	0.849	0.140	

Dry sand/rubber wheel	0.796	0.157	0.681	0.182
Pin on drum	0.772	0.158	0.665	0.177
Jaw crusher	0.732	0.177	0.492	0.215

Source: Ref 24

The alloys in Table 11 are clustered towards the high end of the hardness range. Another jaw crusher test on 28 alloys (Ref 25) shows a more even hardness spread. The correlation coefficients in Table 11 highlight the fallacy of judging manganese steel by its initial (as-heat-treated) hardness, even though there is a direct relationship between this property and abrasion resistance for many carbon and low-alloy steels. One reason for the degradation in correlation coefficient due to the inclusion of manganese steel is that the actual hardness developed at the wear surface because of work hardening is significantly higher. Though 500 to 600 HB is usually considered the limit in service, laboratory studies have shown that the hardness can be as high as 900 HV (Ref 26).

The mediocre correlation coefficients and large standard errors emphasize that laboratory tests are often handicapped by large scatter. Often a certain amount of judgment is necessary to be able to apply the results of laboratory tests to new applications.

The abrasion resistance of austenitic 12 to 14% Mn steels with various carbon contents has been compared with the resistance of other steels and white irons in a jaw crusher abrasion test (see Fig. 17). The wear rate for a quenched and tempered low-carbon low-alloy steel (ASTM 517, type B, at 269 HB), which was used as a comparative standard in each test, is also shown. When the relative wear rate (wear ratio) of each test material is plotted against increasing carbon content on a log-log scale, results for austenitic steels and irons tend to fall on a descending straight line, and results for martensitic steels and irons fall on a parallel line below the line for the austenitic alloys. A decrease in wear ratio represents a proportionate increase in abrasion resistance. Thus, Fig. 17 strongly supports the conclusions that the abrasion resistance of both austenitic and martensitic steels improves with increasing carbon content and that, for a given carbon content, martensitic steels have better abrasion resistance than do austenitic steels. However, martensitic steels and white irons have limited resistance to gouging abrasion because of their lack of toughness. The wear ratios of pearlitic steels, if plotted on Fig. 17, would lie above those of the austenitic steels. There is considerable scatter in the rates for pearlitic steels due to their wide variation in hardness for any given carbon content.

Fig. 17 Relative wear ratios of ferrous alloys in jaw crusher tests. Source: Ref 7

The same trends have been observed in ore milling tests and in sand slurry abrasion tests. Generally, austenitic 12 to 14% Mn steels have higher wear rates, and therefore poorer abrasion resistance than pearlitic or martensitic steels of equivalent carbon content in a low-stress slurry abrasion; a 6Mn-1Mo composition is usually intermediate between pearlitic and martensitic steels in wear resistance.

Note cited in this section

** *The high stress term has been carelessly used and does not apply clearly to a definite condition. Originally used to characterize the AMSCO/Abex wet-sand grinding-abrasion test (Ref 4 and 22 and Table 8), it is not appropriate when applied to a pin being worn by an abrasive anchored on paper or cloth that can have a cushioning effect.

Austenitic Manganese Steels

Corrosion

Manganese steel is not corrosion resistant; it rusts readily. Furthermore, where corrosion and abrasion are combined, as they frequently are in mining and manufacturing environments, the metal may deteriorate or be dissolved at a rate only slightly lower than that of carbon steel. If the toughness or nonmagnetic nature of manganese steel is essential for a marine application, protection by galvanizing is usually satisfactory.

Effects of Temperature

The excellent properties of 13% Mn steel between -45 and 205 °C (-50 and 400 °F) make it useful for all ambient-temperature applications, even in arctic climates. It is not recommended for hot-wear applications because of structural instability between 260 and 870 °C (500 and 1600 °F). At higher temperatures, it may lack the strength and ductility necessary to withstand severe welding stresses, and thus welding must be done under closely controlled conditions. It is not resistant to oxidation, and its creep rupture properties are inferior to those of iron-chromium-nickel austenites. Because the work-hardening rate decreases at higher temperatures, this steel is unsuitable for structural application in the red-heat range.

The effects of temperature on mechanical properties (in both tension and compression) have been well documented (Ref 16, 17, 19). The general trend for changes in flow stress versus temperature is shown in Fig. 18 for both tension and compression. There is an increase in yield strength with decreasing temperature with a corresponding drop in ductility and ultimate tensile strength. The changes in strength and ductility, however, are not uniform, and the steel retains a major portion of its room temperature ductility down to about -100 °C (-150 °F).

Fig. 18 Temperature dependence of flow stresses for equivalent true plastic strain $\bar{\epsilon}_p$, of 0.002, 0.04, 0.08, 0.16, and 0.24. Source: Ref 16

There has been some controversy with respect to the operative mechanism for work hardening in manganese steels at different temperatures. It currently appears that deformation twinning is predominant at the lower temperatures (below about 0 °C, or 30 °F). However, at temperatures above 0 °C (30 °F), strain hardening has been variously attributed to twinning, dynamic strain aging, and stacking fault formation. Some hardening due to the formation of Cottrell clusters and carbide precipitation has been reported at temperatures above 300 °C (570 °F).

At -75 °C (-105 °F), cast manganese steels retain from 50 to 85% of their room-temperature impact resistance (see Table 12). They are considerably more brittle at liquid-air temperature (-185 °C, or -300 °F), but at all atmospheric temperatures encountered by railway track work and mining and construction equipment, they have outstanding toughness that provides a valuable safety factor, compared to ferritic steels at subzero temperatures.

- (b) Held in solid CO₂ and acetone until just before testing.

Associated with the embrittlement produced by reheating above 260 °C (500 °F) are changes in physical properties stemming from the same transformations that cause the loss in toughness. Because both composition and time at temperature influence these changes, erratic behavior and a considerable range in such properties as thermal and electrical conductivity may be expected above 315 °C (600 °F), as shown in Table 13.

(a) Composition: 1.22% C, 13.0% Mn, 0.22% Si, 0.038% P, 0.010% S, 0.07% Ni, 0.03% Cr, 0.07% Cu, 0.004% Al, 0.038% As. Condition: wrought steel, heated to 1050 °C (1925 °F) and air cooled.

(b) Values depend on time at temperature and on amount of transformation.

Thermal-expansion characteristics of austenitic manganese steels are similar to those of other austenitic materials. The expected change in length upon heating is about $1\frac{1}{2}$ times that of ferritic steels. A coefficient of linear thermal expansion of $18 \times 10^{-6}/^{\circ}\text{C}$ ($10 \times 10^{-6}/^{\circ}\text{F}$) is generally precise enough near room temperature (Fig. 19). Transformation to pearlite and the precipitation of carbide influence the values of the expansion of coefficient in the range from 370 to 760 °C (700 to 1400 °F).

Fig. 19 Thermal expansion of a 13% Mn steel. Composition of steel was 1.18C-13Mn-0.5Si. Specimen was

annealed 2 h at 1095 °C (2000 °F) and water quenched. Source: Ref 3

..

Magnetic Properties

The untransformed austenite of 13% Mn steel is virtually nonmagnetic, with a permeability of about 1.03 or less. This permits the use of the material where a strong, tough, nonmagnetic metal is required, as in magnet cover plates, collector shoes for traveling cranes, stator core parts for generators and motors, liner plates for storage bins holding materials that are handled by lifting magnets, magnetic-separator parts, instrument-testing devices, and furnace parts located in the magnetic fields of induction furnaces.

The changes that occur in the composition of the surface during heat treatment may produce a magnetic skin, one that is either a martensitic surface layer or a magnetic oxide. Permeability values of approximately 1.3 have been obtained on specimens that have this magnetic surface layer. Frequently, this layer does no harm, but if necessary, it may be removed by grinding or pickling or it may be prevented altogether by suitable (although often expensive) corrective measures during heat treatment.

Cast or wrought manganese steel is probably the most economical material for strong nonmagnetic parts if machining is not required. Fabrication costs and anticipated operating temperature are decisive factors in selection; operating temperature must not exceed 260 °C (500 °F).

A 20% Mn steel containing bismuth (U.S. Patent 3,010,823) has been developed for nonmagnetic parts that require machining. Laboratory tests indicate a machinability comparable to that of the more expensive type 304 stainless steel that this material was designed to replace. It can be lathe turned (horizontal force: 135 to 380 N at 1.35 m/s, or 30 to 85 lbf at 265 sfm), drilled, and tapped. This steel has not yet been exploited commercially.

Lack of magnetism is a disadvantage when austenitic manganese steel is used in components of material-handling systems that depend on magnetic separators to remove tramp iron from the process stream before it enters crushers, grinders, and other machinery. When there is the possibility that manganese steel parts may become detached from working equipment and fall into the process stream, it is advisable to cast mild steel inserts in the manganese steel parts. The inserts must be large enough to provide the level of ferromagnetism necessary for magnetic separators to detect and remove the lost parts so they cannot enter working machinery and cause damage.

Austenitic Manganese Steels

Welding

Many of the common applications of austenitic manganese steel involve welding, either for fabrication or for repair. Consequently, it is important to understand that this material is unusually sensitive to the effects of reheating, often becoming embrittled to the point of losing its characteristic toughness. Oxyfuel gas welding is so likely to produce embrittlement that it is not accepted as a practical method of welding this alloy. When properly done, electric arc welding is the preferred method of joining or surfacing manganese steels. The phosphorus content is kept below 0.03% to minimize hot cracking. Welding is generally carried out after heat treatment to minimize cracking after deposition of the weld metal.

Arc Welding. Electrodes for arc welding austenitic manganese steel are commercially available in many compositions. They may be used for surfacing, for repair welds, and for joining manganese steel to itself or to carbon steels. Some of them are shown in Table 14. They have a lowered carbon content to minimize carbon precipitation as they cool from the welding temperatures. Though formulated to avoid embrittlement of the deposited filler metal, proper welding procedures still must be used to avoid damage in the heat-affected zone. It is generally recommended that the metal temperature adjacent to the weld not exceed 315 °C (600 °F) after an elapsed time of 1 min.

(a) Covered electrode requirements are described in AWS A5.13-80, "Specification for Solid Surfacing Welding Rods and Electrodes." Bare and covered composite electrodes are described in AWS A5.21-80, "Specification for Composite Surfacing Welding Rods and Electrodes."

(b) Composition given is for deposited weld metal with covered electrodes.

(c) Proprietary electrodes.

Electrodes of high manganese content, containing insignificant amounts of other alloying elements, are also available. Usually, these electrodes are recommended only for the buildup of worn areas, because they are inherently lower in toughness than more highly alloyed grades. High-alloy low-manganese electrodes have not been generally accepted as equivalent to high-manganese types. Austenitic stainless steel electrodes such as type 308 or 310 may be used for the repair of cracks or for the buildup of worn areas.

Factors that are frequently overlooked are the losses in carbon, manganese, and silicon that occur during welding. Although many electrode manufacturers compensate for these losses, improper welding techniques, such as use of excessive arc length and excessive puddling, may cause additional losses. The result is inferior properties in the weld deposit.

Frequently carbon steels are welded to high-manganese steel using austenitic stainless steel electrodes. Because the deposit tends to be a mixture or hybrid of the base and the filler metal, it can have quite different properties. Often it is air hardening, producing a martensitic zone as the weld cools. The ductility of the martensite is low, but the strength is high, and weldments are often satisfactory. The chief adverse factor may be cracks in the martensite. Cross-weld tensile properties of low-carbon 14Mn-1Mo steel plate welded to 1045 steel with EFeMn-A electrodes were 435 MPa (63 ksi) yield strength, 650 MPa (94 ksi) ultimate tensile strength, and 11% elongation with fracture in the 1045 steel. These properties are superior to those of many weldments of carbon steel.

Filler metal from 0.75% C, 15% Mn, 3.5% Ni, and 4.0% Cr seems to be superior to that of EFeMn-A and EFeMn-B.

Grades having chromium at levels above 14% are also useful for the joining of manganese steel and the buildup of worn parts such as trackwork, but because of their low carbon content, have sacrificed abrasion resistance. However, they are more machinable than the higher-carbon grades. If used to restore the dimensions of crusher parts, they should be overlaid with an effective hard-facing alloy.

Precautions. The primary consideration in welding austenitic manganese steel is minimum heating of the parent metal to avoid embrittling transformations or carbide precipitation. This precludes preheating. Under the most favorable circumstances, some precipitation is expected, and the resulting heat-affected zones seldom attain the toughness of normal parent metal. Because manganese steel work hardens in service, it may be assumed that any worn area requiring repair or rebuilding will have a work-hardened surface. This surface must be removed before welding in order to prevent cracking in the heat-affected zone. Also, any fatigue cracks that may have nucleated in the work-hardened region can cause delamination of the weld if not removed.

The low heat conductivity and high thermal expansion of manganese steel also cause difficulties, combining to produce steep thermal gradients and high residual stresses. Weld beads are subjected to tension as they cool. To minimize cracking, it is desirable to peen them while they are hot, producing plastic flow and changing the stress to compression. This hammering should be done promptly after 152 to 229 mm (6 to 9 in.) of weld bead has been deposited. Typical mechanical properties of austenitic manganese steel weld metal are shown in Tables 15 and 16.

Machining

Manganese steels are so tough and work harden at the point of a cutting tool to such an extent that frequently they are considered commercially unmachinable. However, these steels are regularly cut by adhering to generally accepted procedures. In addition, a new, more highly machinable grade of manganese steel has been developed that may be helpful in appropriate applications.

Procedures. Although details of practice and tool design differ, there is general agreement on the procedures for machining manganese steels:

- Machine tools should be rigid and in good condition. Any factors that encourage chatter are undesirable
- Tools should be sharp. Dull tools cause excessive work hardening of the cut surface and accentuate the difficulty in machining
- Low speeds of about 9 to 12 m/min (30 to 40 sfm) should be used. High speeds are likely to create red-hot chips and to cause rapid tool breakdown
- Cobalt high-speed steel tools or tools with cemented carbide and ceramic inserts can be used. The latter are preferred
- The liberal use of a good grade of sulfur-bearing cutting oil is beneficial but not essential
- In castings, holes should be formed by cores in the foundry, rather than by machining, whenever possible
- Coolants are recommended for surface grinding operations

Various sources provide statements in favor of both positive-rake and negative-rake tools and both dry cutting and liquid coolants. Because high temperatures at the cutting edge are a large part of the problem, effective cooling seems desirable. Negative-rake tools are likely to require more force and thus to produce more heat. However, the thinner edge of a positive-rake tool is more vulnerable to heat. Comparative machining data are presented in Table 17.

Table 17 Feed forces required in lathe turning of austenitic manganese steels

Specimens were 31.7 mm (1.25 in.) diam bars, toughened by water quenching. Roughing cuts 2.5 mm (0.098 in.) deep were taken using complex-carbide tools containing about 15% TiC + TaC (predominantly TiC) and about 7 to 10% Co. New cutting edges were used for each positive or negative rake. Cutting speed was 0.19 to 0.20 m/s (37 to 39 sfm).

Type of steel	Feed forces

(a) Recovery of 0.20% Pb from 0.35% added in ladle. The effect on machinability is inclusive.

- (b) Stainless steels suffer in comparison at this speed. They are more machinable at higher speeds and permit certain operations, such as drilling of 6.4 mm ($\frac{1}{4}$ in.) diam holes, which are very difficult with austenitic manganese steel. The type 304 stainless steel was cold finished.

Machinability is increased by the embrittlement that develops with reheating between about 540 and 650 °C (1000 and 1200 °F). Although not usually practicable, such a treatment may be useful if the part can subsequently be properly toughened. Milling usually is not considered practicable.

Machinable Grade. A 20Mn-0.6C steel was developed specifically for improved machinability. Table 18 gives the mechanical properties of this material. Even though the yield strength was deliberately reduced from 360 MPa (52 ksi) to a value between 240 and 310 MPa (35 and 45 ksi) to obtain improved machinability, the ultimate tensile strength exceeds 620 MPa (90 ksi), and elongation in small castings may reach 40%. The heat treatment of this steel involves water quenching from 1040 °C (1900 °F). As-cast properties are lower but are probably adequate for many applications.

Table 18 Typical room-temperature properties of machinable manganese steel

Source: Abex Research Center

This nonmagnetic modified grade can be lathe turned, drilled, tapped, and threaded; even holes 6.4 mm ($\frac{1}{4}$ in.) in diameter can be drilled and tapped in this metal. In some machine shops, it is rated only slightly more difficult to drill than plain 1020 steel, and the quality of the tapped threads is considered very good. Typical machining data for this steel are presented in Table 19. Wear resistance has been sacrificed for machinability, and this grade has significantly less abrasion resistance than do the various types in ASTM A 128.

Table 19 Force requirements for single-point lathe turning of austenitic manganese steel

Type	Condition	Feed force ^(a)				Friction coefficient
		Horizontal		Vertical

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Introduction

STAINLESS STEELS are iron-base alloys containing at least 10.5% Cr. Few stainless steels contain more than 30% Cr or less than 50% Fe. They achieve their stainless characteristics through the formation of an invisible and adherent chromium-rich oxide surface film. This oxide forms and heals itself in the presence of oxygen. Other elements added to improve particular characteristics include nickel, molybdenum, copper, titanium, aluminum, silicon, niobium, nitrogen, sulfur, and selenium. Carbon is normally present in amounts ranging from less than 0.03% to over 1.0% in certain martensitic grades.

The selection of stainless steels may be based on corrosion resistance, fabrication characteristics, availability, mechanical properties in specific temperature ranges and product cost. However, corrosion resistance and mechanical properties are usually the most important factors in selecting a grade for a given application.

Original discoveries and developments in stainless steel technology began in England and Germany about 1910. The commercial production and use of stainless steels in the United States began in the 1920s, with Allegheny, Armco, Carpenter, Crucible, Firth-Sterling, Jessop, Ludlum, Republic, Rustless, and U.S. Steel being among the early producers.

Only modest tonnages of stainless steel were produced in the United States in the mid-1920s, but annual production has risen steadily since that time. Even so, tonnage has never exceeded about 1.5% of total production for the steel industry. Table 1 shows shipments of stainless steel over a recent 10-year period. Production tonnages are listed only for U.S. domestic production. France, Italy, Japan, Sweden, the United Kingdom, and West Germany produce substantial tonnages of steel, and data on production in these countries are also available. However, other free-world countries do not make their figures public, and production statistics are not available from the U.S.S.R. or other Communist nations, which makes it impossible to estimate accurately the total world production of stainless steel.

Table 1 Total U.S. shipments of stainless steel over the 10-year period from 1979 to 1988

Year	Shipments	
	kt	1000 tons
1979	1234	1361
1980 ^(a)	1022	1127
1981 ^(a)	1055	1163
1982 ^(a)	811	894
1983 ^(a)	1032	1137

The development of precipitation-hardenable stainless steels was spearheaded by the successful production of Stainless W by U.S. Steel in 1945. Since then, Armco, Allegheny-Ludlum, and Carpenter Technology have developed a series of precipitation-hardenable alloys.

The problem of obtaining raw materials has been a real one, particularly in regard to nickel during the 1950s when civil wars raged in Africa and Asia, prime sources of nickel, and Cold War politics played a role because Eastern-bloc nations were also prime sources of the element. This led to the development of a series of alloys (AISI 200 type) in which manganese and nitrogen are partially substituted for nickel. These stainless steels are still produced today.

New refining techniques were adopted in the early 1970s that revolutionized stainless steel melting. Most important was the argon-oxygen-decarburization (AOD) process. The AOD and related processes, with different gas injections or partial pressure systems, permitted the ready removal of carbon without substantial loss of chromium to the slag. Furthermore, low carbon contents were readily achieved in 18% Cr alloys when using high-carbon ferrochromium in furnace charges in place of the much more expensive low-carbon ferrochromium. Major alloying elements could also be controlled more precisely, nitrogen became an easily controlled intentional alloying element, and sulfur could be reduced to exceptionally low levels when desired. Oxygen could also be reduced to low levels and, when coupled with low sulfur, resulted in marked improvements in steel cleanliness.

During the same period, continuous casting grew in popularity throughout the steel industry, particularly in the stainless steel segment. The incentive for continuous casting was primarily economic. Piping can be confined to the last segment to be cast such that yield improvements of approximately 10% are commonly achieved. Improvements in homogeneity are also attained.

Over the years, stainless steels have become firmly established as materials for cooking utensils, fasteners cutlery, flatware, decorative architectural hardware, and equipment for use in chemical plants, dairy and food-processing plants, health and sanitation applications, petroleum and petrochemical plants, textile plants, and the pharmaceutical and transportation industries. Some of these applications involve exposure to either elevated or cryogenic temperatures; austenitic stainless steels are well suited to either type of service. Properties of stainless steels at elevated temperatures are discussed in the section "Elevated-Temperature Properties" of this article and more detailed information is available in the article "Elevated-Temperature Properties of Stainless Steels" in this Volume. Properties at cryogenic temperatures are discussed in the section "Subzero-Temperature Properties" of this article.

Modifications in composition are sometimes made to facilitate production. For instance, basic compositions are altered to make it easier to produce stainless steel tubing and castings. Similar modifications are made for the manufacture of stainless steel welding electrodes; here, combinations of electrode coating and wire composition are used to produce desired compositions in deposited weld metal.

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Classification of Stainless Steels

Stainless steels are commonly divided into five groups: martensitic stainless steels, ferritic stainless steels, austenitic stainless steels, duplex (ferritic-austenitic) stainless steels, and precipitation-hardening stainless steels.

Martensitic stainless steels are essentially alloys of chromium and carbon that possess a distorted body-centered cubic (bcc) crystal structure (martensitic) in the hardened condition. They are ferromagnetic, hardenable by heat treatments, and are generally resistant to corrosion only to relatively mild environments. Chromium content is generally in the range of 10.5 to 18%, and carbon content may exceed 1.2%. The chromium and carbon contents are balanced to ensure a martensitic structure after hardening. Excess carbides may be present to increase wear resistance or to maintain cutting edges, as in the case of knife blades. Elements such as niobium, silicon, tungsten, and vanadium may be added to modify the tempering response after hardening. Small amounts of nickel may be added to improve corrosion resistance in some media and to improve toughness. Sulfur or selenium is added to some grades to improve machinability.

Ferritic stainless steels are essentially chromium containing alloys with bcc crystal structures. Chromium content is usually in the range of 10.5 to 30%. Some grades may contain molybdenum, silicon, aluminum, titanium, and niobium to confer particular characteristics. Sulfur or selenium may be added, as in the case of the austenitic grades, to improve

machinability. The ferritic alloys are ferromagnetic. They can have good ductility and formability, but high-temperature strengths are relatively poor compared to the austenitic grades. Toughness may be somewhat limited at low temperatures and in heavy sections.

Austenitic stainless steels have a face-centered cubic (fcc) structure. This structure is attained through the liberal use of austenitizing elements such as nickel, manganese, and nitrogen. These steels are essentially nonmagnetic in the annealed condition and can be hardened only by cold working. They usually possess excellent cryogenic properties and good high-temperature strength. Chromium content generally varies from 16 to 26%; nickel, up to about 35%; and manganese, up to 15%. The 2xx series steels contain nitrogen, 4 to 15.5% Mn, and up to 7% Ni. The 3xx types contain larger amounts of nickel and up to 2% Mn. Molybdenum, copper, silicon, aluminum, titanium, and niobium may be added to confer certain characteristics such as halide pitting resistance or oxidation resistance. Sulfur or selenium may be added to certain grades to improve machinability.

Duplex stainless steels have a mixed structure of bcc ferrite and fcc austenite. The exact amount of each phase is a function of composition and heat treatment (see the article "Cast Stainless Steels" in this Volume). Most alloys are designed to contain about equal amounts of each phase in the annealed condition. The principal alloying elements are chromium and nickel, but nitrogen, molybdenum, copper, silicon, and tungsten may be added to control structural balance and to impart certain corrosion-resistance characteristics.

The corrosion resistance of duplex stainless steels is like that of austenitic stainless steels with similar alloying contents. However, duplex stainless steels possess higher tensile and yield strengths and improved resistance to stress-corrosion cracking than their austenitic counterparts. The toughness of duplex stainless steels is between that of austenitic and ferritic stainless steels.

Precipitation-hardening stainless steels are chromium-nickel alloys containing precipitation-hardening elements such as copper, aluminum, or titanium. Precipitation-hardening stainless steels may be either austenitic or martensitic in the annealed condition. Those that are austenitic in the annealed condition are frequently transformable to martensite through conditioning heat treatments, sometimes with a subzero treatment. In most cases, these stainless steels attain high strength by precipitation hardening of the martensitic structure.

Standard Types. A list of standard types of stainless steels, similar to those originally published by the American Iron and Steel Institute (AISI), appears in Table 2. The criteria used to decide which types of stainless steel are standard types have been rather loosely defined but include tonnage produced during a specific period, availability (number of producers), and compositional limits. Specification-writing organizations such as ASTM and SAE include these standard types in their specifications. In referring to specific compositions, the term type is preferred over the term grade. Some specifications establish a series of grades within a given type, which makes it possible to specify properties more precisely for a given nominal composition.

(a) Single values are maximum values unless otherwise indicated.

(b) Optional

In each of the three original groups of stainless steels--austenitic, ferritic, and martensitic--there is one composition that represents the basic, general-purpose alloy. All other compositions derive from this basic alloy, with specific variations in composition being made to impart very specific properties. The so-called family relationships for these three groups are summarized in Fig. 1, 2, and 3. Type 329 is a duplex stainless steel (about 80% ferrite, 20% austenite as annealed) and is listed separately in Table 2.
